Abstract. During the intensive observation period of the Watershed Allied Telemetry Experimental Research (WATER), a total of 1074 raindrop size distribution were measured by the Parsivel disdrometer, the latest state-of-the-art optical laser instrument. Because of the limited observation data in Qinghai-Tibet Plateau, the modelling behaviour was not well done. We used raindrop size distributions to improve the rain rate estimator of meteorological radar in order to obtain many accurate rain rate data in this area. We got the relationship between the terminal velocity of the raindrop and the diameter (mm) of a raindrop: \( v(D) = 4.67D^{0.53} \). Then four types of estimators for X-band polarimetric radar are examined. The simulation results show that the classical estimator \( R(Z_H) \) is most sensitive to variations in DSD and the estimator \( R(K_{DP}, Z_H, Z_{DR}) \) is the best estimator for estimating the rain rate. An X-band polarimetric radar (714XDP) is used for verifying these estimators. The lowest sensitivity of the rain rate estimator \( R(K_{DP}, Z_H, Z_{DR}) \) to variations in DSD can be explained by the following facts. The difference in the forward-scattering amplitudes at horizontal and vertical polarizations, which contributes \( K_{DP} \), is proportional to the 3rd power of the drop diameter. On the other hand, the exponent of the backscatter cross-section, which contributes to \( Z_H \), is proportional to the 6th power of the drop diameter. Because the rain rate \( R \) is proportional to the 3.57th power of the drop diameter, \( K_{DP} \) is less sensitive to DSD variations than \( Z_H \).

1 Introduction

The quantitative estimation of rain rates using the meteorological radar has been one of the main themes in radar meteorology and radar hydrology. The conventional single-polarized Doppler radar uses the measurement of radar reflectivity, radial velocity and the storm structure to infer some aspects of hydrometeor types and amounts. The relationships between the rain rate \( R \) and the radar reflectivity factor \( Z_H \) (\( Z_H - R \) relations) have been widely used to estimate rainfall amounts. However, the classic rain estimation method has many sources of error (e.g., Joss and Waldvogel, 1990; Collier, 1996). The sensitivity of \( Z_H - R \) relations to variations in raindrop size distributions (DSD) is the major source of error. Raindrop size distributions are determined by microphysical processes such as coalescence and breakup, condensation, evaporation and melting of snowflakes, etc. DSD also changes in time and space, in correspondence with changes in the microphysical process in a given precipitation system. Battan (1973) obtained a total of 69 \( Z_H - R \) relationships to show that there was large variability in \( Z_H - R \) relationships caused by natural variations in DSD. Atlas et al. (1984) showed, from an analysis of experimental drop size spectra, that the average estimation error due to variations in DSD would be about 33%.

With the advent of dual-polarized radar techniques it is generally possible to achieve significantly higher accuracies in the estimation of hydrometeor types and in some cases of hydrometeor amounts. In contrast to conventional radars, which use \( Z_H - R \) relationships to estimate rain rates, polarimetric radars use polarimetric parameters, such as differential reflectivity \( Z_{DR} \) and specific differential phase \( K_{DP} \). Because of being less sensitive to natural variations in the DSD, the polarimetric parameters are used in improving the
quantitative estimation of rain rates. Seliga and Bringi (1976) first showed that $Z_{DR}$ could be used to retrieve raindrop size distributions and can improve rain rate estimation methods. The usage of differential phase to improve rain rate estimation was proposed theoretically (Seliga and Bringi, 1978) and is now recognized as an essential parameter for polarimetric radar measurements by Ryzhkov and Zrnic (1995, 1996). Most research in the field of radar polarimetry, as applied to rainfall parameter estimates, has been performed for the radar wavelengths at S-band, such as Sachidananda and Zrnic (1986), Chandrasekar et al. (1990). There are the wavelengths of operational radars in many countries (e.g., the S-band Weather Surveillance Radar-1988 Doppler (WSR-88D) network in the United States). Longer radar wavelengths (such as those at S-band) are the obvious choice for measurements in moderate and heavy rain because of low attenuation and backscatter phase shifts effects. Partial attenuation of radar signals is already a problem at C-band frequencies. Research studies on the C-band wavelength were done by May et al. (1999), Carey et al. (2000), Keenan et al. (2001) and Bringi et al. (2001a). Many researches and operational meteorological radars employ shorter wavelengths, such as those at X-band. The partial attenuation effects at X-band are more severe when compared with those at C-band, and accounting for these effects has been a significant problem for quantitative estimates of rainfall parameters based on reactivity measurements at these wavelengths. Chandrasekar et al. (2002) analysed the error structure at the X-band, using a similar method as Chandrasekar et al. (1990) and showed that the $R$ ($K_{DP}$) was relatively insensitive to DSD variations. A unique dataset consisting of high-resolution polarimetric radar measurements and dense rain gauge and disdrometer observations collected in east-central Florida during the summer of 1998 was examined by Brandes et al. (2002). All of the above validation studies have shown that there is an improvement in rainfall estimation if a dual-polarization radar is used and polarimetric rainfall estimation techniques are more robust with respect to DSD variations than the conventional $R$ ($Z_H$) relations. At the moment, however, there is no consensus on the degree of improvement and the choice of an optimal polarization relation. The most significant improvement was reported in the latest study in Oklahoma (Ryzhkov et al., 2002) using the $R$ ($K_{DP}$, $Z_{DR}$) relation. Relatively modest improvement was observed in Florida (Brandes et al., 2002, 2003, 2004) with the best results obtained from the $R$ ($Z_H$, $Z_{DR}$) relation.

Scattering simulation is the most adequate method for clarifying the effect of DSD variations. This method is used in studies done by Sachidananda and Zrnic (1986), Chandrasekar et al. (1990) and Matrosov et al. (1999). In this work, we use three parameter distributions to study quantitatively the statistical errors of polarimetric rain rate estimators due to DSD variations, and use polarization radar parameters $Z_{DR}$ and $K_{DP}$ to improve the quantitative estimation of the rain rate.

2 Objectives of the experiment

The following scientific questions will be explored in this work.

1. The raindrop’s terminal velocity is an important parameter in the microphysical process. The relationship between the terminal velocity and the raindrop size plays an important role in estimating the rain rate. This will be given in Sect. 4.2

2. Although the relationships between the rain rate $R$ and the radar reflectivity factor $Z_H$ ($Z_H - R$ relations) have been widely used to estimate rainfall amounts, they have many sources of error. Why $Z_H - R$ relations are not one and only for rain rate estimating is also an important objective. The explanation will be given in Sect. 5.

3. The polarimetric parameters are used in improving the quantitative estimation of rain rates. We get four types of estimators with polarimetric parameters to explain the polarimetric radar is superior to conventional single-polarized Doppler radar in Sect. 6.

3 Experiment

The experiment area was carried out in the northeast of Qinghai-Tibet Plateau, (38.85° N, 100.41° E), and the altitude is 1515 m. This area is in the midstream of the Heihe basin. This basin is very important for the Northwestern China, because they are not only the bases of agriculture, but also offer a better microclimatic environment for developing the ecosystem. The arid region of the basin is one of the main arid regions in the world and its mountain topography forms the particular sight pattern of “glacier-river-oasis-desert” which is linked by water. The raindrop size data were collected from May to July 2008, during the second part of the Watershed Allied Telemetry Experimental Research (WATER) project (Li et al., 2009).

The disdrometer used is OTT Parsivel made by Germans. The new generation of Parsivel disdrometer provides the latest state-of-the-art optical laser technology. It is subsequently classified into 32 classes of sizes and terminal velocities. The OTT Parsivel has been described extensively by Yuter et al. (2006). An X-band polarimetric radar (714XDP) has a Vaisala Sigmet Digital IF Receiver and Signal Processor RVP8 was used in the Watershed Allied Telemetry Experimental Research (WATER) (Li et al., 2009) and thirty rain rate gauges were used for testing the rain rate estimators. In these raindrop distribution data and rain rate data, we made a distinction between stratiform and convective rainfall. Separation of convective and stratiform rain was carried out by visual inspection of RHIs from the X-band polarimetric radar.
The shape of a falling raindrop is determined by a balance of three types of forces working on the drop surface: hydrostatic pressure, surface tension and aerodynamic pressure. While a small drop has a spherical shape, a larger drop tends to have an oblate spheroid shape with a slightly flatter base. This characteristic of a raindrop shape is essential for polarimetric radar measurements of rainfall. The axis-ratio formulas used in the present study are:

\[ \alpha = \frac{1.0048 + 0.0057D_e - 2.628D_e^2 + 3.682D_e^3}{1.677D_e^{1/3}} D_e < 0.11 \text{ cm}, \quad D_e > 0.44 \text{ cm} \]

\[ \alpha = 1.012 - 0.144D_e - 1.03D_e^2, \quad 0.11 \text{ cm} \leq D_e \leq 0.44 \text{ cm} \]

where \( D_e \) is the volume-equivalent spherical diameter (in centimetres). Equation (1) is for equilibrium axis ratios derived from the numerical model of Beard and Chuang (1987), and Eq. (2) is the axis ratio fit obtained from laboratory and field measurements by Andsager et al. (1999).

### 4.2 Rain rate and terminal velocity of raindrops

When the drop size distribution is given, the rain rate \( R \) (mm h\(^{-1}\)) can be calculated by:

\[ R = 0.6\pi \times 10^{-3} \int_{D_{\text{min}}}^{D_{\text{max}}} D^3 v(D) N(D) dD \]

where \( D \) is the diameter (mm) of a raindrop, \( D_{\text{max}} \) is the maximum drop diameter, \( v(D) \) is the terminal velocity (m s\(^{-1}\)) of the drop in still air and \( N(D) d(D) \) the number of drops (m\(^{-3}\)) in the diameter interval \( D \) to \( D + dD \). Table 1 shows the terminal velocity of the raindrop with different diameters. The terminal velocity and raindrop diameters are obtained from PASIVEL directly and it determines the terminal velocity and diameter as an approximate value. For example, if a raindrop’s diameter is 0.2 mm which is smaller than the first measured value (0.31 mm), PASIVEL will determine the raindrop’s diameter as 0.31 mm. In Table 1 one point contained lots of raindrop diameters. The average atmospheric pressure of the ground was 840 mb and the average temperature on the ground was 20°C for these raindrop data. Then we measured the air density of the ground as 1.0 kg m\(^{-3}\). Beard (1976) obtained the resulting formulas for the terminal velocity in three diameter ranges (0.5 µm–19 µm, 19 µm–1.07 mm, 1.07 mm–7 mm). These diameter ranges are used to calculate the terminal velocity directly from the equivalent spherical diameter and the physical properties of the drop and atmosphere. Foote and du Toit (1969) assumed the air density was reduced to a value of 0.66 kg m\(^{-3}\) at 500 mb. The velocity for large raindrops is seen to increase considerably from a sea level value of 9 m s\(^{-1}\) to a 500 mb value in excess of 12 m s\(^{-1}\). We compared our result to the relation given by, for example, Beard. The result is also shown in Table 1 as follows. From the table, we found our observed terminal velocity was higher than Beard’s result for the same temperature and air density. Figure 1 shows the curves using the method of least squares for the terminal velocity of the raindrop with different diameters. Obtain a relationship: \( v(D) = 4.67D^{0.53} \).
4.3 Polarimetric parameters

The reflectivity factor is defined by:

\[
Z_{H,V} = \frac{\lambda^4}{\pi^3} \left[ \frac{m^2 + 1}{m^2 - 1} \right] \int_{D_{\min}}^{D_{\max}} \sigma_{H,V}(D) N(D) dD
\]  

(4)

where \( \lambda \) is the radar wavelength, \( m \) the complex refractive index of water and \( \sigma_{H,V} \) is the backscatter cross-section at horizontal and vertical polarizations.

The differential reflectivity \( Z_{DR} \) (dB) is defined by:

\[
Z_{DR} = 10\log\left(\frac{Z_H}{Z_V}\right) = 10\log\left(\frac{\int_{D_{\min}}^{D_{\max}} \sigma_H(D) N(D) dD}{\int_{D_{\min}}^{D_{\max}} \sigma_V(D) N(D) dD}\right)
\]  

(5)

The differential reflectivity \( Z_{DR} \) is a measure of the reflectivity-weighted mean axis ratio of the hydrometeors in a radar sampling volume which is defined by the radar beam width and the pulse width.

The specific differential phase \( K_{DP} \) (deg km\(^{-1}\)) is defined by:

\[
K_{DP} = \frac{180}{\pi} \text{Re} \int_0^{D_{\max}} \left[ f_H(D) - f_V(D) \right] N(D) dD
\]  

(6)

where \( \text{Re} \) refers to the real part of the integral, \( f_H \) and \( f_V \) are the forward-scattering amplitudes at horizontal (H) and vertical (V) polarizations, respectively.

5 Classic estimation methods of rain rate

The sensitivity to natural variations in DSD is a substantial source of error in classic estimators of rain rate \( R \). This is due to the fact that the \( R - Z_H \) relation is not a one-to-one relation; the same \( Z_H \) does not necessarily give the same \( R \) and the same \( R \) does not necessarily give the same \( Z_H \) because \( Z_H \) and \( R \) depend on different moments of the DSD. Under Rayleigh scattering, \( Z_H \) is proportional to \( D^6 \) while \( R \) is proportional to \( D^{3.53} \). These facts can be explained by way of the observed DSD examples shown in Fig. 2a which has the approximate \( Z_H \) values but different rain rates (4.3, 6.7, and 8.0 mm\( h^{-1} \)). The differences in the rain rate are due to the difference in the drop density of smaller drops; the DSD sample of \( R = 8.0 \text{ mm}\( h^{-1} \) has a larger number of drops for \( D = 1 - 3 \text{ mm} \) compared to the other DSD samples. Figure 2b shows three examples of drop size distributions that have the same rain rate \( R (0.2 \text{ mm}\( h^{-1} \) ), but different reflectivity factors \( Z_H (13, 15, \text{ and } 16 \text{ dBZ}) \). In contrast to the case of the rain rate, the difference in reflectivity factors can be explained by the difference in the number density of larger drops; the DSD sample of \( Z_H = 16 \text{ dBZ} \) has the larger number density for the drops \( D > 1.5 \text{ mm} \). This opposite dependency of \( R \) and \( Z_H \) on drop size \( D \) is due to the fact that \( Z_H \) is proportional to \( D^6 \), while \( R \) is proportional to \( D^{3.53} \).

\( R \) and \( Z_H \) are dependent on different moments of the DSD. Thus, natural variations in DSD cause large dispersions in \( R - Z_H \) scatter plots. Classifying rain type (convective and stratiform rain) is one of the useful techniques for improving the accuracy of classic estimators \( R (Z_H) \). Scatter plots of \( R - Z_H \) relations is shown in Fig. 3, respectively, where y-axis taking logarithm, for convective and stratiform rain. \( R \) of each point are calculated directly from 30 second-averaged DSD. From Fig. 3, we found \( R \) and \( Z_H \) obey the relationship: \( R = a \times 10^b \times Z_H \). The obtained \( R - Z_H \) relations for stratiform rain, convective rain and all rain types are \( R = 3.2 \times 10^{-2} \times 10^{0.653 \times Z_H} \), \( R = 4.6 \times 10^{-2} \times 10^{0.058 \times Z_H} \) and \( R = 3.0 \times 10^{-2} \times 10^{0.06 \times Z_H} \), respectively.

Several combinations of polarimetric variables are possible for constructing rain rate estimators. The simplest method is an estimator which uses only \( K_{DP} \). Scatter plots of \( R - K_{DP} \) relations is shown in Fig. 4, for stratiform rain and convective rain. From Fig. 4, we found \( R \) and \( K_{DP} \) obey the relationship: \( R = a + b \times K_{DP} \). The obtained \( R - K_{DP} \) relations for stratiform rain and convective rain are \( R = 0.07907 + 1.74788 \times K_{DP} \) and \( R = 0.027 + 2.122 \times K_{DP} \), respectively.

It has been recognised for a long time that the X-band wavelength was not useful for accurate rainfall measurements because of the rain attenuation problem of \( Z_H \). However, this situation changed dramatically after polarimetric radar, which measures differential phase and the specific differential phase \( K_{DP} \), became available. In addition to the less sensitivity of differential phase to DSD variations, it is immune to radar hardware calibration problems, which are one of the major sources of error for signal power measurements and also immune to rain attenuation. Differential phase measurements are less affected by the presence of hail, which causes overestimation of the rain rate in the case of classic \( R (Z_H) \) estimator. The differential phase can be used to correct the reflectivity factor for loss due to beam blockage by topography, attenuation and anomalous propagations (Ryzhkov and Zrnic, 1996; Ryzhkov et
Dear editor,

Firstly, thank you very much for your hard work for this manuscript. The manuscript has been checked carefully. In addition, some typing mistakes have been found. A point-by-point reply to the black boxes has been given as follows.

Black box 1: The reference should been removed.
Black box 2: The missing reference has been given as follow.
Black box 3: The missing reference has been given as follow.
Black box 4: The missing reference has been given as follow.
Black box 5: The tables' number should be 2a and 2b.
Black box 6: The reference should be Park et al. (2005).

Fig. 3. Scatter plots of the radar reflectivity (Z) and the rain rate (R).

Fig. 4. Scatter plots of the specific differential phase (K_{DP}) and the rain rate (R).
al., 2000). Because of these advantages, it is important to construct rain estimators using a combination of polarimetric variables such as \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \). So we use the relationships: \( R = a \times I_{DP}^{\theta} \times Z_{DR}^{b} \) and \( R = a \times I_{DP}^{\theta} \times Z_{DR}^{b} \). A nonlinear regression analysis was applied to the data to obtain the coefficients of these estimators. The results are shown in Tables 2a and b.

The comparisons of rain rates \( R \) calculated from estimators \( R (Z_H) \), \( R (K_{DP}) \), \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \) with rain rates \( R_{dis} \) calculated from observed raindrop size spectra are shown in Figs. 5 and 6 for stratiform rain and convective rain, respectively. Scatter plots suggest that, of the four estimators, \( R (K_{DP}, Z_H, Z_{DR}) \) is the most accurate estimator from the viewpoint of the insensitivity to variations in DSD. The worst estimator is \( R (Z_H) \), which is most sensitive to variations in DSD.

To quantitatively examine the uncertainty of the four estimators, \( R (Z_H) \), \( R (K_{DP}) \), \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \), due to the variations in DSD, two types of errors were calculated: The mean percentage normalized error (MPNE) and the mean percentage root-mean-squared error (MPRMSE). These errors are defined as:

\[
\text{MPNE} = \frac{1}{n} \sum_{n} \left( \frac{|R_{cal} - R_{dis}|}{R_{dis}} \right) / n \tag{7}
\]

\[
\text{MPRMSE} = \frac{1}{n} \sum_{n} \left( \frac{(R_{cal} - R_{dis})^2}{R_{dis}} \right) / n \tag{8}
\]

There, \( R_{cal} \) means rain rates calculated from estimators, \( R_{dis} \) means rain rates calculated from observed raindrop size spectra, \( <> \) means the average for a certain interval of rain rate. We take the certain interval as \( R < 0.5 (\text{mm h}^{-1}) \), \( 0.5 \leq R < 1 \), \( 1 \leq R < 2 \), \( 2 \leq R < 4 \) for stratiform rain, and \( R < 1 (\text{mm h}^{-1}) \), \( 1 \leq R < 2 \), \( 2 \leq R < 5 \), \( 5 \leq R < 10 \), \( 10 \leq R < 18 \) for convective rain, \( n \) means the number of the rain rate interval.

The MPNE of \( R (Z_H) \), \( R (K_{DP}) \), \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \) for stratiform rain are 32.0%, 18.2%, 15.0%, and 12.3%, respectively. The MPNE of \( R (Z_H) \), \( R (K_{DP}) \), \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \) for convective rain are 28.8%, 16.8%, 14.2% and 11.3%, respectively. The MPRMSE of \( R (Z_H) \), \( R (K_{DP}) \), \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \) for stratiform rain are 33.2%, 19.1%, 15.1% and 13.3%, respectively. The MPRMSE of \( R (Z_H) \), \( R (K_{DP}) \), \( R (Z_H, Z_{DR}) \) and \( R (K_{DP}, Z_H, Z_{DR}) \) for convective rain are 30.8%, 16.9%, 14.0% and 10.3%, respectively. From these comparisons, we can conclude that \( R (K_{DP}, Z_H, Z_{DR}) \) is the least sensitive to variations in DSD.

Although error analysis based on the comparisons of radar estimates with gauge measurements is not necessarily an appropriate method to confirm the sensitivity of rain rate estimators to variations in DSD, it may be useful to know the total performance of rain rate estimators. The values of errors obtained from the radar-gauge analysis are usually larger than those of the simulation because error sources other than DSD variations can be commonly introduced: for example, errors due to the difference in time and space for measurements, due to evaporation, or due to attenuation correction of \( Z_H \) and \( Z_{DR} \). From the comparison of radar estimated rainfall amount with rain gauge data, Park et al. (2005) showed that the normalized error of attenuation corrected \( R (Z_H) \), and the normalized error of \( R (K_{DP}) \) are 26% and 21%, respectively, for 15-min rainfall accumulations and 19% and 11%, respectively, for one-hour rainfall accumulations.

There is a convective rain process and eight gauges received rain rate data on 13 June 2008.

We used the X-band polarimetric radar and these gauges to test rain rate estimators. The radar data quality has been corrected before used. The shape of raindrops can be approximated by oblate spheroids for light rain. Radar and in situ aircraft-based observations show that, on average, the raindrops are oriented with the symmetry axis in the vertical direction. This implies that the shape of raindrops seen at an elevation angle of 90 is nearly circular. Therefore, \( Z_{DR} \) measurements performed with the antenna pointing at an elevation of 90 should be 0 dB. However, if there is nonzero \( Z_{DR} \) due to the system bias, it does not change with the different H and V orientations looking vertical. In many radars, the different H and V orientations can be achieved by changing the azimuth positioning over zero to 360, keeping the elevation angle at 90. However, the exact procedure depends on the set up of the scanning servo system of the radar. In summary, the average \( Z_{DR} \) computed with all possible orientations of the polarization states of the radar antenna pointing in the vertical direction should be zero. Figure 7 shows the meanvalue of the \( Z_{DR} \) is 0.6 for 88° elevation. This is the system deviation. It is well known that convective storms cause significant attenuation and differential attenuation at X-band. As a consequence, radar measurements of reflectivity and differential reflectivity must be corrected for rain attenuation before they can be used quantitatively. In addition, Polarimetric radars at X-band have one important advantage, the specific differential phase \( K_{DP} \) is much larger than that at longer wavelengths. From scattering simulations, compared to C and S-bands, respectively, \( K_{DP} \) at X-band is larger by about 1.5 and 3 times for the same rain rate. We used the \( K_{DP} \) to correct the attenuated \( Z_H \) and \( Z_{DR} \) (Bringi, 2001b). The specific attenuation (\( A_H \)) and the specific differential attenuation (\( A_{DP} \)) can be obtained as follows:

\[
A_H = a_1 \cdot Z_H^\beta \quad (Z_H < 25 dBz) \tag{9}
\]

\[
A_H = a_1 \cdot K_{DP} \quad (Z_H \geq 25 dBz) \tag{10}
\]

\[
A_{DP} = a_2 \cdot A_H^\gamma \quad (Z_H < 25 dBz) \tag{11}
\]

\[
A_{DP} = a_2 \cdot K_{DP} \quad (Z_H \geq 25 dBz) \tag{12}
\]

Then, \( Z_H \) and \( Z_{DR} \) can be corrected as follows:

\[
Z_H(r) = Z_{H_0}(r) + 2 \int_0^r A_H(s) ds \tag{13}
\]

Fig. 5. Scatter plots of $R_{\text{dis}}$ calculated from measured drop size distribution and $R$ estimated by four types for rain rate estimators (a) $R(Z)$, (b) $R(K_{DP})$, (c) $R(Z, Z_{\text{DR}})$ (d) $R(K_{DP}, Z, Z_{\text{DR}})$.

Fig. 6. Scatter plots of $R_{\text{dis}}$ calculated from measured drop size distribution and $R$ estimated by four types for rain rate estimators (a) $R(Z)$, (b) $R(K_{DP})$, (c) $R(Z, Z_{\text{DR}})$ (d) $R(K_{DP}, Z, Z_{\text{DR}})$.
rate estimators to natural variations in DSD. Most of the previous studies evaluated polarimetric estimators, comparing radar estimates with surface gauge measurements. It is well known that the difference between radar estimates and rain gauge data is due not only to the accuracy of the rain rate estimator to variations in DSD, but also to other factors, such as differences in the sampling volume size, differences in the observation height, accuracy of the radar system calibration, etc. The results of our simulations show that the estimator \( R (K_{DP}, Z_H, Z_{DR}) \) is less sensitive to natural variations in DSD than the classical estimator \( R (Z_{DR}) \). The mean percentage normalized error (MPNE) of \( R (Z_H) \) and \( R (K_{DP}, Z_H, Z_{DR}) \) for stratiform rain and convective rain are 32.0%, 12.3% and 28.8%, 11.3%, respectively. The lower sensitivity of \( R (K_{DP}, Z_H, Z_{DR}) \) and the higher sensitivity of \( R (Z_H) \) to variations in DSD can be explained by the fact that the difference between the forward-scattering amplitudes at horizontal (H) and vertical (V) polarizations \( f_H(D) - f_V(D) \) in the definition of \( K_{DP} \) is proportional to the 3rd power of the diameter of a raindrop for the monodisperse DSD model, while the reflectivity factor \( Z_H \) is proportional to the 6th power of the diameter.
