Abstract. This work investigates the trade-off between increases in vegetation water use and rain water infiltration afforded by soil improvement after reforesting severely degraded grassland in the Lesser Himalaya of central Nepal. The hillslope hydrological functioning (surface and subsurface soil hydraulic conductivities and overland flow generation) and the evapotranspiration (rainfall interception and transpiration) of the following contrasting vegetation types were quantified and examined in detail: (i) a nearly undisturbed, natural broadleaved forest; (ii) a 25-year-old, intensively-used pine plantation; and (iii) a highly degraded pasture. Planting pines increased vegetation water use relative to the pasture and natural forest situation by 355 and 55 mm year⁻¹, respectively. On balance, the limited amount of extra infiltration afforded by the pine plantation relative to the pasture (only 90 mm year⁻¹ due to continued soil degradation associated with regular harvesting of litter and understory vegetation in the plantation) proved insufficient to compensate the higher water use of the pines. As such, observed declines in dry season flows in the study area are thought to mainly reflect the higher water use of the pines although the effect could be moderated by better forest and soil management promoting infiltration. In contrast, a comparison of the water use of the natural forest and degraded pasture suggests that replacing the latter by (mature) broadleaved forest would (ultimately) have a near-neutral effect on dry season flows as the approximate gains in infiltration and evaporative losses were very similar (ca. 300 mm year⁻¹ each). The results of the present study underscore the need for proper forest management for optimum hydrological functioning as well as the importance of protecting the remaining natural forests in the region.

1 Introduction

The traditional view of forest hydrological functioning, in which wet season rainfall is readily absorbed and stored for subsequent gradual release during the dry season, has often been likened to a “sponge” (Hamilton and King, 1983). Although the forest sponge effect had been the subject of debate before (cf. reviews of older literature by Andréassian, 2004; Bruijnzeel, 2004; Galudra and Sirait, 2009), the concept came under severe scrutiny in the early 1980s when Bosch and Hewlett (1982) reviewed the results from nearly 100 paired catchment experiments around the globe. They concluded that “no experiments in deliberately reducing vegetation cover caused reductions in water yield, nor have any deliberate increases in cover caused increases in yield”. As such, the removal of a dense forest cover was seen to lead to higher streamflow totals, and reforestation of open lands to a decline in overall streamflow. These initial results were confirmed by several subsequent reviews, both for the (warm) temperate zone (Stednick, 1996; Brown et al., 2005; Jackson...
et al., 2005) and the humid tropics (Bruijnzeel, 1990; Grip et al., 2005; Scott et al., 2005). Whilst the majority of experiments concerned small catchments (< 2 km²), comparable results of increased water yield following forest removal and reduced flows following reforestation were also obtained for much larger river basins (1100–175 000 km²; Trimble et al., 1987; Madduma Bandara, 1997; Costa et al., 2003; Zhou et al., 2010). The fact that the bulk of the change in streamflow associated with such experiments was observed during conditions of baseflow (Bosch and Hewlett, 1982; Bruijnzeel, 1989; Farley et al., 2005) at first sight contradicted the reality of the forest sponge concept, and its very existence became questioned (Hamilton and King, 1983; Calder, 2005). Indeed, since the early reviews of Bosch and Hewlett (1982) and Hamilton and King (1983), many have emphasised the more “negative” aspects of forests, such as their high water use or inability to prevent extreme flooding (e.g. Calder, 2005; FAO-CIFOR, 2005; Jackson et al., 2005; Kaimowitz, 2005) rather than focus on the positive functions of a good forest cover, including the marked reduction of surface erosion and shallow landslip occurrence (Sidle et al., 2006), improved water quality (Bruijnzeel, 2004; Wohl et al., 2012), moderation of all but the largest peak flows (Roa-Garcia et al., 2011; Ogden et al., 2013) or carbon sequestration (Farley et al., 2005; Malmer et al., 2010).

At the same time, there is ample evidence of severe and widespread soil degradation after tropical forest conversion to unsustainable forms of land use (e.g. overgrazed pastures, subsistence cropping on steep slopes without adequate soil conservation measures, etc.; Oldeman et al., 1991; Bai et al., 2008). In addition, the area occupied by impervious surfaces such as roads, trails, built-up areas and yards is also on the increase (Ziegler and Giambelluca, 1997; Rijsdijk et al., 2007; Sidle and Ziegler, 2012). This is often accompanied by strongly increased stormflow volumes during times of rainfall (Bruijnzeel and Bremmer, 1989; Fritsch, 1993; Chandler and Walter, 1998; Zhou et al., 2002; Ziegler et al., 2004; Ziegler et al., 2007) and shortages of water during extended dry periods (Bartarya, 1989; Madduma Bandara, 1997; Bruijnzeel, 2004; Tiwari et al., 2011). Such changes in streamflow regime effectively reflect the loss of the former forest sponge (cf. Roa-Garcia et al., 2011; Krishnaswamy et al., 2012; Ogden et al., 2013) through critically reduced replenishment of soil water and groundwater reserves due to lost surface infiltration opportunities, despite the fact that the lower water use of the post-forest vegetation should have produced higher streamflows throughout the year (Bruijnzeel, 1986, 1989).

Reforestation of degraded land in the tropics is often conducted in the expectation that disturbed streamflow regimes (commonly referred to as the “too little–too much syndrome”: Bartarya, 1989; Schreier et al., 2006) will be restored by the increased rainfall absorption afforded by soil improvement after tree planting (Scott et al., 2005: cf. Ilstedt et al., 2007). At the same time, the water use of fast-growing tree plantations tends to be (much) higher than that of the degraded vegetation they typically replace – particularly where the trees have access to groundwater (Calder, 1992; Kallarackal and Somen, 1997). Furthermore, major improvements in the (near-)surface infiltration capacity of severely degraded soils, after tree planting may well take several decades of undisturbed forest development to fully materialise (Gilmour et al., 1987; Scott et al., 2005; Bonell et al., 2010). As such, reforesting degraded pasture or shrub land may well cause already diminished dry season flows to become reduced even further, depending on the net balance between increases in soil water reserves through improved infiltration versus decreases caused by the higher plant water uptake (the so-called “infiltration trade-off” hypothesis; Bruijnzeel, 1986, 1989).

Although the overwhelming majority of paired catchment experiments have shown major decreases in baseflow volumes, after the establishment of a tree cover on non-forested land (Farley et al., 2005) this does not disprove the possibility of enhanced dry season flows after reforestation at the small catchment scale. As pointed out by Bruijnzeel (2004) and Malmer et al. (2010), only three out of the 26 paired catchment studies of the hydrological impacts of reforestation reviewed by Jackson et al. (2005) and Farley et al. (2005) were located in the tropics (where soil degradation tends to be more acute; Oldeman et al., 1991; Bai et al., 2008) whereas none of the experiments represented degraded soil conditions. In other words, no positive effects of reforestation on soil water intake capacity could manifest and the observed reductions in water yield simply reflected the higher water use of the trees compared to the grasses and scrubs they replaced (cf. Trimble et al., 1987; Waterloo et al., 1999; Scott and Prinsloo, 2008).

Nevertheless, although direct evidence for the infiltration trade-off hypothesis seemed to be lacking until recently (see below), several hillslope-scale or small-basin studies of the hydrological impacts of reforesting severely degraded land (discussed in some detail by Scott et al., 2005) observed reductions in stormflow volumes that were likely to exceed the estimated corresponding increases in vegetation water use (cf. Zhang et al., 2004; Sun et al., 2006). Unfortunately, as the catchments involved in these experiments were either too small or leaky to sustain perennial streamflow, the expected net positive effect of forestation on dry season flows could not be ascertained in these cases (Scott et al., 2005; cf. Chandler, 2006). However, recently published concurrent reductions in stormflow response to rainfall, and positive trends in baseflow over time since reforesting severely degraded land in southern China (Zhou et al., 2010) and South Korea (Choi and Kim, 2013), or along a forest degradation–recovery gradient in the Western Ghats of India (Krishnaswamy et al., 2012, 2013) are highly suggestive of a net positive outcome of the infiltration trade-off mechanism.

A related aspect concerns the vexed question whether or to what extent (or at what scale) reforestation may have a
positive influence on the amount of precipitation received. Although it is clear that tree planting at the local scale (< 50 km) cannot be expected to have such an effect (Harding, 1992), claims of a positive effect of large-scale forestation on rainfall generation are becoming more frequent (see Ellison et al., 2011, for an in-depth discussion). At the same time, re-establishing forest cover over an area of ca. 67 000 km² of wasteland over a period of 50 years in southern China did not produce any change in rainfall (Zhou et al., 2010). Furthermore, in a particularly comprehensive observational study of Amazonian rainfall and its dependence on vegetation (Angelini et al., 2011), isotopic analysis showed the precipitation to originate mostly from large-scale weather systems linking the interior region to the ocean and precipitation to derive only very partly from local evaporation. Nevertheless, there are some indications that large-scale deforestation may negatively affect rainfall during the transition from wet season to dry season in mainland Southeast Asia (Kamae et al., 2001; cf. Kumagai et al., 2013) and therefore it cannot be excluded that the reverse case also applies (Spracklen et al., 2012). All in all, in the absence of strong empirical evidence of a major effect of tree plantation on rainfall, it is difficult to take into account any possibly positive influence at this stage.

The Middle Mountain zone of the Nepalese and Indian Himalayas provides another case in point regarding the need to restore diminished dry season flows. The rivers originating in this densely populated part of the mountain range (Singh et al., 1984; Hrabovszky and Miyan, 1987) are mostly rainfed and thus do not benefit from increased water yields from melting glaciers under a changing climate scenario (Bookhagen and Burbank, 2010; Andermann et al., 2012; Immerzeel et al., 2013). Land surface degradation in the zone has often progressed to a point where rainfall infiltration has become seriously impaired and overland flow is rampant (Bruijnzeel and Bremmer, 1989; Gerrard and Gardner, 2002; cf. Ghimire et al., 2013), with reduced dry season flows as the result (Bartraya, 1989; Tiwari et al., 2011; Tyagi et al., 2013). Partly in response to the latter problem, some 23 000 ha of severely degraded pastures and shrublands in the Middle Mountain zone of central Nepal were planted to fast-growing coniferous tree species (mainly *Pinus roxburghii* and *P. patula*) between 1980 and 2000 (District Forest Offices, Kabhre and Sindhupalchok, unpublished data, 2010). However, villagers and farmers in central Nepal have expressed serious concerns about diminishing spring discharges and dry season flows following the large-scale plantation of the pines (República, 2012). Such considerations assume added importance under the strongly seasonal climatic conditions prevailing in the Middle Mountain zone where ≥ 80 % of the annual rainfall falls during the main monsoon (June–September; Merz, 2004; Bookhagen and Burbank, 2010) and where water during the dry season is already at a premium (Merz et al., 2003).

There is a dearth of sound experiments in the Himalayan region to ascertain the hydrological effects of land use change (reviewed by Bruijnzeel and Bremmer, 1989; Negi, 2002) and indeed for the (sub)tropics in general with respect to the extent to which reforestation of degraded land can improve or even restore diminished dry season flows (Scott et al., 2005; Zhou et al., 2010; Krishnaswamy et al., 2013; Choi and Kim, 2013). In view of the difficulty of identifying catchments with a single dominant land cover type (e.g. forest or grassland) as well as being sufficiently large to support perennial flows (required for the evaluation of changes in baseflows during the extended dry season) in this rugged and spatially highly variable terrain (Maharjan, 1991; Merz, 2004; Bookhagen and Burbank, 2006), the present study opted for the “space for time substitution approach” in which experimental plots with contrasting land-cover types were studied in terms of their hydrological processes and taking the infiltration trade-off hypothesis as a starting point. Thus, the primary objective of the present study was to investigate the trade-offs between the changes in water use going from a severely degraded pasture to a mature coniferous tree plantation or well-developed broadleaved forest on the one hand, and the concurrent increases in soil water reserves afforded by improved rainfall infiltration after plantation or forest maturation on the other in a typically Middle Mountain zone setting in central Nepal. Total vegetation water use (evapotranspiration, ET), overland flow production and field-saturated soil hydraulic conductivity profiles with depth were determined in a little disturbed natural broad-leaved forest, a highly degraded pasture, and in a mature 25-year-old planted pine forest near Dhulikhel. The resulting data were used to address the central question: can reforestation of severely degraded hill slopes in the heavily populated Nepalese Middle Mountain zone restore diminished dry season flows upon plantation maturation?

### 2 Methods

#### 2.1 Site description

The Middle Mountain zone or Lesser Himalaya, which is situated between ~800 and ~2400 m above mean sea level (a.m.s.l.) and which occupies about 30 % of Nepal, is home to ca. 45 % of the country’s population (based on the 2011 population census; http://cbs.gov.np/). The zone is characterised by a complex geology which has resulted in equally complex topography, soil and vegetation patterns (Dobremez, 1976). The geology of the central Nepalese Middle Mountains consists chiefly of phyllites, schists and quartzites (Stocklin and Bhattarai, 1977). Depending on elevation, the climate is humid subtropical to warm temperate and strongly seasonal, with most of the rain falling between June and September. Rainfall varies with elevation and exposure to the prevailing monsoonal air masses (Merz, 2004; cf. Bookhagen and Burbank, 2006). Between 1000 and 2000 m a.m.s.l. the natural vegetation consists of a largely evergreen mixed
broadleaved forest dominated by *Schima wallachii* and various chestnuts and oaks (*Castanopsis* spp., *Quercus* spp.), with *Rhododendron arboreum* as their main associate above ca. 1500 m a.m.s.l. Due to the prevailing population pressure, much of this species-rich forest has disappeared (< 10 % remaining), except on slopes that are too steep for agricultural activity (Dobremez, 1976; Merz, 2004).

The present study was conducted in the Jiku Khola catchment (JKC) (Fig. 1). The 111.4 km² JKC (27°35′–27°41′ N, 85°32′–85°41′ E) is situated approximately 45 km east of Kathmandu (the capital of Nepal) along the Araniko Highway in the Kabhre District between 796 and 2019 m a.m.s.l. The general aspect of the catchment is southeast and the topography ranges from flat valleys to steep upland slopes (Maharjan, 1991). The geology consists of sedimentary rocks affected by various degrees of metamorphism and includes phyllites, quartzites, and various schists (Nakarmi, 2000). In general, soils in the upper half of the JKC are Cambisols (FAO, 2007) of loamy texture and moderately well to rapidly drained (Maharjan, 1991).

The climate of the JKC is largely humid subtropical, grading to warm temperate around 2000 m a.m.s.l. Mean (±SD, standard deviation) annual rainfall measured at mid-elevation (1560 m a.m.s.l.) for the period 1993–1998 was 1487 (±155) mm (Merz, 2004). The main seasons are the rainy season (monsoon; June–September), the pre-monsoon (October–November), winter (December–February), and the post-monsoon (March–May). During the monsoon about 80 % of the total annual precipitation falls. In general, July is the wettest month with about 27 % of the annual rainfall. The driest months are November–February, each accounting for about 1 % of the annual rainfall (Merz, 2004). About 40–50 % of monsoon rainfall occurs as small showers (< 5 mm) while larger storms (> 30 mm) are comparatively infrequent (< 8 %). Maximum rainfall intensities are in the order of 75–85 mm h⁻¹ (based on 5-min observations) but median values are low at 2–2.5 mm h⁻¹ (Ghimire et al., 2012). Average monthly temperatures as measured at 1560 m a.m.s.l. range from 7.7 °C in January to 22.6 °C in June while the average monthly relative humidity varies from 55 % in March to 95 % in September. Strong winds are common during thunderstorms before the onset of the main monsoon, but these are momentary and the average monthly wind speeds are always less than 2 m s⁻¹ and show only slight seasonal variation. Annual reference evaporation ETo (Allen et al., 1998) for the period 1993–2000 was 1170 mm (Merz, 2004). Vegetation cover in the catchment consists of ~30 % forest (both natural and planted), 7 % shrubland and 6 % grassland, with the remaining 57 % largely under agriculture (Merz, 2004). The JKC was subjected to active reforestation until 2004 as part of the Nepal–Australia Forestry Project (NAFP).

We measured vegetation water use (wet- and dry-canopy evaporation), overland flow and saturated soil hydraulic conductivity (*Kfs*) in natural forest, degraded pasture and planted forest. The land use at the respective research sites can be characterised as follows:

**Natural Forest:** this site (elevation 1500 m a.m.s.l., northwest exposure, average slope angle 24°) consisted of dense, largely evergreen forest facing little anthropogenic pressure. The 14.0 ± 2.2 m high forest had a well-developed understory and litter layer with visual evidence of soil faunal activity in the form of a high carbon content and numerous near-surface macropores. Tree density in the 50 m × 50 m plot as measured in May 2011 was 1869 trees ha⁻¹, whereas the average diameter at breast height (DBH) for trees with DBH ≥ 5 cm was 13.6 ± 4.4 cm and the corresponding basal area 27.1 m² ha⁻¹. The forest was floristically diverse. More than half of the trees consisted of *Castanopsis tribuloides* (65 %) followed by *Schima wallachii* (16 %), *Myrica escu- lenta* (6 %), *Rhododendron arboreum* (5 %), *Quercus lamellosa* (4 %) and various other species (4 %). Although largely evergreen, the natural forest sheds a small proportion of its leaves towards the end of the dry season (February–March) but recovers quickly thereafter. For example, the maximum measured leaf area index (LAI, using a Licor 2000 Plant Canopy Analyzer) was 5.43 ± 0.12 (SD) in September 2011 (i.e. at the end of the rainy season), while corresponding values measured during the premonsoon period in March, April and early June were 4.52 ± 0.19, 5.14 ± 0.09, and 5.32 ± 0.10, respectively. The soil was classified as a Cambisol of clay loam texture. Clay content varied little with depth between 5 and 100 cm (26–29 %) as did the sand (24–26 %) and silt (44–48 %) contents. Soil organic carbon (SOC) declined from 4.10 ± 0.25 % at 5–15 cm depths to 0.72 ± 0.13 % between 50 and 100 cm depths. The topsoil had a low bulk density (0.93 ± 0.08 g cm⁻³ at 5–15 cm). During soil profile excavations and in road exposures, roots were observed to penetrate into the underlying (weathered) bedrock. Depth to bedrock within the 50 m × 50 m plot was ca. 2.3 m. Further information on changes in soil characteristics with depth at this and the other two research sites is given by Ghimire et al. (2013).

**Degraded Pasture:** this 50 m × 120 m site (1620 m a.m.s.l., southeasterly exposure, average slope angle 18°) has been heavily grazed for more than 150 years according to various local sources and is crossed by numerous footpaths. It is located ~2700 m from the natural forest plot (Fig. 1). Numerous patches of compacted or bare soil surface were evident. The dominant grass and herb species included *Imperata cylindrica*, *Saccharum spontaneum*, and *Ajuga macrop-lerma*. Little or no grass cover remained at the peak of the dry season (March–May). The Cambisol underneath the degraded pasture plot had a silty clay texture, with a lower clay content (12–19 %) and a higher sand content (34–44 %) than the soil of the natural forest plot. Because of the intensive grazing and frequent human traffic, topsoil bulk density in the degraded pasture was significantly higher (1.18 ± 0.33 g cm⁻³) than in the natural forest. Depth to bedrock within the plot was determined at 2.4 m.
Pine Forest: this former degraded pasture located approximately 400 m from the studied degraded pasture on a 20° slope of southwesterly exposure at an elevation of 1580 m a.m.s.l. was planted with *P. roxburghii* in 1986. The pine trees in the 60 m × 60 m plot were 25 years old at the start of field work in June 2010. No other tree species were recorded in the plot. An understory was largely absent as grazing by cattle is common. In addition, the local population collects the litter for animal bedding and regularly harvests the grassy herb layer. Pruning of trees for fuelwood, and felling for timber are also common in the pine forests of the JKC (Schreier et al., 2006; cf. Ghimire et al., 2013a) although the research plots themselves remained free from such major disturbances throughout the present investigation. Like the dominant trees in the natural broadleaved forest, the evergreen *P. roxburghii* trees shed a proportion of their needles towards the end of the dry season but also recovered their foliage fairly quickly thereafter. The LAI of the pine forest plot was estimated at 2.21 ± 0.10 in September 2011 whereas corresponding values during the premonsoon period in March, April and early June were 2.05 ± 0.14, 2.15 ± 0.12, and 2.17 ± 0.11, respectively. The stem density, mean DBH and basal area as measured in May 2011 were 853 trees ha⁻¹, 23.65 ± 3.8 cm and 37.6 m² ha⁻¹, respectively. The average tree height was estimated at 16.3 ± 3.82 m. The Cambisol underneath the pine forest plot had a silty clay texture, with a lower clay content (11–19 %) and a (much) higher sand content (40–47 %) than the soil of the natural forest or degraded pasture. Because of the regular collection of litter and associated exposure of the soil surface with erosive canopy drip, topsoil organic carbon in the pine forest was much lower (1.7 ± 0.3 %) and bulk density significantly higher (1.24 ± 0.10 g cm⁻³) than in the natural forest. Roots were observed to penetrate into the underlying (weathered) bedrock which occurred at a depth of ca. 1.5 m.

2.2 Field measurements

2.2.1 Environmental monitoring

Climatic conditions were monitored by an automatic weather station located in the degraded pasture site at a distance of 400 m from the pine forest plot (Fig. 1). In addition, incident rainfall (*P*, mm) for each plot was recorded using a tipping bucket rain gauge (Rain Collector II, Davis Instruments, USA; 0.2 mm per tip) backed up by a manual gauge (100 cm²) that was read daily at ca. 08:45 LT (local time). Incoming short-wave radiation (*Rₛ*) at the pasture station was measured using an SKS 110 pyranometer (Skye Instruments, UK). The resulting radiation loads were corrected for slope aspect for use at the natural- and pine-forest sites. Air temper-
ature ($T$, °C) and relative humidity (RH, percentage of saturation) were measured at 2 m height using a Vaisala HMP45C probe protected against direct sunlight and precipitation by a radiation shield. Wind speed and wind direction were measured at 3 m height, using an A100R digital anemometer (Vector Instruments, UK) and W200P potentiometer (Vector Instruments, UK), respectively. All measurements were recorded at 5 min intervals by a Campbell Scientific Ltd. 23X data-logger. Soil water content at each plot was measured at a single location at depths of 10, 25, 50, and 75 cm using TDR (time domain reflectometry) sensors (CS616, Campbell Scientific Ltd.) at 30 min intervals.

2.2.2 Forest hydrological measurements

Wet-canopy evaporation or rainfall interception ($E_i$) was calculated as the difference between gross rainfall ($P$) and net rainfall (throughfall + stemflow). Throughfall ($T_f$, mm) in the natural and pine forest plots was measured daily using 10 (pine plot) or 15 (natural forest) funnel-type collectors (154 cm² orifice) that were regularly relocated in a random manner (cf. Holwerda et al., 2006). In addition, $T_f$ was recorded continuously using three tilted stainless steel gutters in each plot (200 cm × 30 cm × 15 cm each). The throughfall measurements were carried out from 20 June to 9 September, 2011 (81 days), thereby covering the bulk of the 2011 rainy season. Stemflow ($S_f$, mm) was measured on 10 trees which were representative of the dominant species in the natural forest plot and similarly on eight trees in the pine forest plot. Stemflow was collected using 10 L buckets connected to flexible polythene tubing fitted around the circumference of the trunk in a spiral fashion at 1 m from the ground. Stemflow measurements were carried out for 65 days between 28 July and 1 October 2010. $S_f$ was not measured during the 2011 rainy season. Instead, the average values derived for the 2010 rainy season (expressed as a fraction of $P$) were used when estimating and modelling interception losses for 2011. Annual interception losses were estimated using the revised analytical model of Gash et al. (1995) which was run on a daily basis for the year between 1 June 2010 and 31 May 2011 using the forest structural and average evaporation model parameters established by Ghimire et al. (2012) for the same sites and daily rainfall values as input. A crossed sensitivity analysis was conducted using daily rainfall data from either forest site in the model to examine the effect of potentially contrasting rainfall amounts between the two sites on modelled rainfall interception totals. No significant difference was found, reflecting the fact that the distribution of daily rainfall at the two forest sites was not statistically different ($p < 0.05$). For a more detailed description of the measuring and modelling procedures used in the derivation of annual totals of $T_f$, $S_f$ and $E_i$, the reader is referred to Ghimire et al. (2012).

The quantification of tree transpiration ($E_t$) was accomplished by in situ xylem sap flow rate measurements. Sap flow measurements on individual trees involve the measurement of xylem sap flux density and sapwood cross-sectional area (Granier, 1985; Lu et al., 2004; Lubczynski, 2009). Sap flux density $J_p$ was measured primarily using thermal dissipation probes (TDP; Granier, 1985) because of their low cost, easy installation and overall simplicity, while the heat field deformation method (HFD; Nadezhdhina et al., 2012), and the heat ratio method (HRM; Burgess et al., 2001) were used in addition for the purpose of deriving radial sap flow patterns. Sapwood cross-sectional area was estimated from wood cores using an increment borer at breast height (Grissonio-Mayer, 2003). Long-term monitoring of $J_p$ was conducted on nine trees in the natural forest plot that were considered representative in terms of the dominant species present and overall size class distribution, and similarly on six trees in the pine forest plot between June 2010 and May 2011. Radial sap flow patterns were measured using the HFD method on eight trees in the pine forest and on two $C. tribuloides$ trees in the natural forest for at least 3 consecutive days per tree. Similarly, radial sap flow patterns for two other dominant species ($S. wallichii, n = 2$; $M. esculenta, n = 1$) were derived using the HRM. In addition, a sap flow campaign was held from March to May 2011 to capture the sap flow of additional trees that were not covered by the long-term monitoring. A total of 48 additional trees were monitored in the pine forest (distributed over four additional 30 m × 30 m plots) vs. 24 trees in the natural forest (two additional 30 m × 30 m plots) during this campaign using a single TDP sensor per tree. Tree-scale measurements of $J_p$ were scaled up to the plot level using least-squares regressions between total trunk cross-sectional area and corresponding sapwood area, relations between sapwood area and $J_p$, and information on radial changes in $J_p$ for different tree species before summing the water uptake by all individual trees in a plot to give stand transpiration. For further details on the measurement of $J_p$, gap filling and the scaling exercise the reader is referred to Ghimire (2014b).

To obtain approximate annual ET totals for the two forests, the respective values of wet- and dry-canopy evaporation (i.e. $E_i$ and $E_t$) were added and combined with estimates for evaporation from the understory (natural forest only given the absence of understory vegetation in the pine stand; Ghimire et al., 2014b) and from the litter layer based on findings obtained at other sites having comparable forest structural and climatic characteristics. In view of the high LAI of the natural forest (5.4), its northwesterly exposition and the generally low wind speeds, evaporative contributions by the understory were expected to be modest. Motzer et al. (2010) determined the evaporative fraction contributed by the understory at 20% of that by the overstory in a lower montane forest of comparable stature and LAI in Ecuador. This value was adopted for the Dhulikhel natural forest. Corresponding evaporation from litter layer ($E_s$) was considered to be low for the reasons given above and in view of the strongly seasonal rainfall regime which causes the forest floor to be
moist for four months only. Comparative measurements of $E_s$ in subtropical broadleaved forests are rare but Kelliher et al. (1992) determined a value of 0.3 mm d$^{-1}$ in a well-watered New Zealand forest. Translating this finding to the Dhulikhel situation and assuming the bulk of $E_s$ to take place during the rainy season (4 months) gave an estimated value of 35 mm year$^{-1}$. Effectively the same result (36 mm year$^{-1}$) was obtained when applying the ratio of $E_s$ to $E_t$ derived for the same New Zealand forest (0.18; Kelliher et al., 1992) to the Dhulikhel forest. Thus, a value of 35 mm year$^{-1}$ was adopted as a first estimate for $E_s$ in the natural forest. For the more open pine forest (LAI, 2.2), one expects $E_s$ to be somewhat higher than in the nearby natural forest. However, the pine litter is typically harvested by local people after the main leaf-shedding period (Ghimire et al., 2013, 2014a), reducing amounts of litter present and thus its moisture retention capacity. Further, a substantial fraction of the rainfall in the pine forest runs off as overland flow (see Results below), reducing $E_s$ even further. Waterloo et al. (1999) determined $E_s$ in a similarly stocked stand of Pinus caribaea in Fiji at 9% of the Penman open water evaporation, $E_o$. Applying the same fraction and taking again an effective period of 4 rainy months yielded an estimated $E_s$ for the Dhulikhel pine forest of ca. 35 mm year$^{-1}$.

### 2.2.3 Soil hydraulic conductivity and inferred hillslope hydrological pathways

Field-saturated soil hydraulic conductivity ($K_{fs}$) (Talsma and Hallam, 1980; Reynolds et al., 1985) in the respective plots was measured both at the surface and at depths of 0.05–0.15, 0.15–0.25, 0.25–0.50, and 0.5–1.0 m. The $K_{fs}$ at different depths were subsequently combined with selected percentiles of 5 min maximum rainfall intensities (RI$\text{max}$) to infer the dominant hillslope hydrological response during intense rainfall following Chappell et al. (2007). A disc permeameter (Perroux and White, 1988; Mckenzie et al., 2002) was used for the measurement of surface $K_{fs}$ in the field and a constant-head well permeameter (CHWP; Talsma and Hallam, 1980) for the measurement of $K_{fs}$ in deeper layers. Use of the CHWP was restricted to the dry season to minimise errors from smearing of the auger hole walls (Chappell and Lancaster, 2007). For surface $K_{fs}$, 10 (pine forest) to 17 (degraded pasture) replicate measurements were made whereas for subsurface $K_{fs}$, 45–80 auger holes were used per site. For a detailed description of the measuring procedures and sampling strategy, the reader is referred to Ghimire et al. (2013).

### 2.2.4 Overland flow

Overland flow (OF) at the natural forest, degraded pasture and pine forest sites was monitored between 20 June and 9 September 2011 (i.e. the bulk of the 2011 rainy season) using a single, large (5 m $\times$ 15 m) runoff plot per land-cover type. Runoff was collected in a gutter funnelling the water to a first 180 L collector equipped with a seven-slot divider system allowing only one-seventh of the spillover into a second 180 L drum, thereby bringing the total collector capacity to 1440 L ($\sim$ 20 mm). The water levels in the two collectors were measured continuously using a pressure transducer device (Keller, Germany) placed at the bottom. Collectors were emptied and cleaned after measuring the water level manually every day at around 08:45 LT. Event runoff volume was calculated by converting the water levels to volumes using a precalibrated relationship per drum and summing up to obtain total runoff volume. Measured overland flow volumes were corrected for direct rainfall inputs into the runoff collecting system. Overland flow volumes were divided by the projected plot area to give overland flow in millimetres per event.

### 2.2.5 Grassland evaporation

The HYDRUS-1D model for one-dimensional soil water movement (Šimůnek et al., 2008) was used to estimate evaporation from the degraded pasture site. Like most pastures in the area, the site was heavily overgrazed (Gilmour et al., 1987; Ghimire et al., 2014a, b) and the capacity of the grass to intercept rainfall was considered negligible. Likewise, in view of the very limited live biomass of the grass, transpiration was also considered minimal. Hence, overall, evaporation at the grassland site was set equal to soil evaporation defined by HYDRUS-1D model (Šimůnek et al., 2008). The HYDRUS-1D model is based on the modified Richard’s equation. In this study it was assumed that the gaseous phase plays an unimportant role in the overall vapour transport due to thermal gradients.

The modelling was divided into three parts: (i) model calibration against measured soil moisture data (1 September–30 November 2010) using optimisation, (ii) model validation using data collected between 1 February and 31 March 2011, and (iii) complete simulation of soil water dynamics and evaporation for the entire annual period (1 June 2010–31 May 2011). The 1 m-deep soil column was divided into four schematic layers as follows: (i) 0–0.15 m, (ii) 0.15–0.25 m, (iii) 0.25–0.50 m, and (iv) 0.50–1.0 m.

The soil physical parameters employed in HYDRUS-1D include $Q_r$ for the residual water content and $Q_s$ for the saturated water content, as well as the two parameters, $\alpha$ and $n$, describing the shape and range of the soil water retention curve and the derived relative hydraulic conductivity curve (Van Genuchten, 1980). Other model parameters include the saturated hydraulic conductivity ($K_s$), and $I$, a pore-connectivity parameter. All parameters were optimised except for $K_s$ which was measured separately for each layer in the field using well permeametry as described above. The parameters were optimised by fitting observed and modelled soil moisture values using the Marquardt–Levenberg optimisation algorithm. The model was run on an hourly basis. The boundary conditions used in the model were the atmospheric
boundary (soil surface) with surface runoff occurrence, and free drainage at the lower boundary.

3 Results

3.1 Evapotranspiration

Figure 2 shows the monthly variation in ET and its two main components, rainfall interception and transpiration, for the three land-cover types studied between 1 June 2010 and 31 May 2011 whereas the respective seasonal and annual evapotranspiration totals are presented in Table 1.

Although the seasonal patterns for ET were similar between vegetation types, monthly ET totals were generally higher for the planted pine forest and lower in the degraded pasture throughout the monitoring period (Fig. 2). All three sites showed higher ET rates and monthly totals during the wet season months (June–September) compared to the dry season months (October–April), with the transitional month of May (marking the first return of the rains; Fig. 2a) showing intermediate values. Such findings can be attributed largely to the (much) higher frequency of wetting and subsequent drying (evaporation) during the wet season (cf. Table 1).

As found earlier for monthly ET totals, the annual ET for the planted forest was the highest for all three vegetation types studied (577 mm), being two and a half times larger than the annual ET in the degraded pasture (225 mm; Table 1). The annual ET for the natural forest was 524 mm, which is 53 mm less than that for the nearby pine forest but 300 mm higher than the ET of the degraded pasture (Table 1). Whilst absolute rainfall interception totals did not differ much between the natural and the planted forest (31 mm year$^{-1}$ higher in the broadleaved forest despite a slightly lower rainfall total), both the seasonal and annual transpiration totals were distinctly higher for the pine forest (Table 1). Wet-season transpiration in the pine forest was 20 mm higher vs. 64 mm during the dry season.

3.2 Soil hydraulic conductivity, overland flow and subsurface flow paths

As expected on the basis of the degree of anthropogenic pressure experienced by the respective sites, the median surface $K_{fs}$ was lowest for the degraded pasture (18 mm h$^{-1}$) and highest for the natural forest (232 mm h$^{-1}$), such that the two differed by more than an order of magnitude (Fig. 3). The most striking feature of the $K_{fs}$ data set is that the me-

Figure 4. Amounts of rainfall, throughfall and overland flow (mm) during the 2011 monsoon measuring campaign (20 June–9 September) in a natural forest, a degraded pasture, and a mature, intensively used pine plantation near Dhulikhel, central Nepal. Note that values for the natural forest plot were normalised for rainfall amount to allow for more direct comparisons.

Kfs derived for the 0.05–0.15 m depth interval in the natural forest (82 mm h⁻¹; Fig. 3), it cannot be excluded that at least some of the recorded overland flow was contributed by the saturation-excess type (SOF) (Bonell, 2005). The median surface Kfs values in the degraded pasture and pine forest were below the upper quartile of RI₅max, thereby indicating the frequent occurrence of IOF during high-intensity rainfall (Fig. 3). Indeed, overland flow at the degraded pasture site was typically generated after 3–4 mm of rain while the seasonal (monsoonal) overland flow total amounted to 187 mm (21.3 % of incident rainfall; Fig. 4). Corresponding values for the pine forest were comparable at 4.2 mm of rain before overland flow would start and a seasonal total of 136 mm (15.5 % of rainfall and 18.6 % of throughfall; Fig. 4).

With regard to Kfs in the 0.05–0.15 m layer, although the upper quartile of RI₅max exceeded the median Kfs values for this depth interval at both the degraded pasture and pine forest sites (Fig. 3), the actual volumes of water reaching this layer are necessarily restricted by the low value of the surface “throttle” at both sites. Surface Kfs at either site did not exceed the Kfs at 0.05–0.15 m depth and therefore no perched water table can develop and hence no shallow lateral subsurface stormflow (SSF) is generated at either site. In contrast, the corresponding median Kfs at the natural forest is still above (or nearly equal to) most 5 min rainfall intensities, thereby favouring mostly vertical percolation at this site. For the 0.15–0.25 and 0.25–0.50 m depth intervals, the Kfs values in the natural forest indicated a similar hydrological response to extreme rainfall, namely mostly lateral SSF because of limited vertical percolation under such conditions (cf. Fig. 3). Finally, at 1.0 m depth, the differences in Kfs and inferred hydrological response to rainfall became insignificant between sites (Fig. 3).

3.3 Site water budgets

Combining the above mentioned overland flow percentages for the pine forest and degraded pasture with a long-term mean annual site rainfall of 1500 mm (Merz, 2004), the difference in approximate annual IOF between the two land
Table 2. Summary of changes in annual ET (mm) and OF (mm), and the resultant gains in infiltration (mm) and evaporative losses (mm) when converting degraded pasture to (heavily used) planted pine forest or (little disturbed) natural broadleaved forest near Dhulikhel, central Nepal. Note that overland flow amounts were calculated for a mean annual site rainfall of 1500 mm (Merz, 2004). Note that all values are rounded off to the nearest fifth or tenth.

covers represents a gain in infiltration of approximately 90 mm year$^{-1}$ under the planted pine forest relative to the degraded grass land (Table 2). However, the relative amounts of surface evaporation/transpiration in the degraded pasture and the pine forest, plus the added rainfall interception losses from the pine forest, suggest a difference in annual evapotranspiration of $\sim$350 mm year$^{-1}$ after reforestation and stand maturation (Table 2). Thus, the added loss through ET is greatly in excess of the estimated gain in infiltration of 90 mm year$^{-1}$ after reforestation causing a net loss of $\sim$260 mm year$^{-1}$. Repeating the exercise for the natural forest (with an estimated annual ET of $\sim$525 mm and very low overland flow production) suggests the approximate gain in infiltration (285 mm year$^{-1}$) and the extra evaporative loss (300 mm year$^{-1}$) are both very similar (Table 2), implying no major change in moisture availability and dry season flow under mature natural forest conditions.

4 Discussion and conclusions

4.1 Human impact on forest hydrological functioning – an understudied dimension

The results obtained for the respective water balance components suggest that soil water replenishment and retention during the monsoon are largely controlled by surface and subsurface soil hydraulic conductivities and the resultant partitioning of rainfall into overland flow, lateral subsurface flow and deep percolation (Table 1, Fig. 3). As long as rainfall intensities remain below the surface $K_{fs}$ threshold for overland flow to occur, soil water reserves are being recharged. However, for intensities above this threshold a major proportion of the rain is redirected laterally over the surface as overland flow and less water is available for soil moisture replenishment. The high surface and near-surface $K_{fs}$ in the natural forest (82–232 mm h$^{-1}$) ruled out IOF occurrence and favour vertical percolation. In contrast, the corresponding $K_{fs}$ values for the planted forest and degraded pasture were conducive to IOF generation during medium- to high-intensity storms which represents an important net loss of moisture to these hill slopes (Fig. 3, Table 2).

Marked reductions in surface- and near-surface $K_{fs}$ after converting tropical forest to grazed pasture have been observed in many cases (Alegre and Cassel, 1996; Tomasella and Hodnett, 1996; Deuchars et al., 1999; Zimmermann et al., 2006; Molina et al., 2007; Tobón et al., 2010) and the Himalayas are no exception (Patnaik and Virdi, 1962; Gilmour et al., 1987; Gerrard and Gardner, 2002; Ghimire et al., 2013, 2014a). The low surface and near-surface $K_{fs}$ reported for grazing conditions is mostly the result of destroyed macroporosity through trampling by cattle and by the much diminished soil faunal activity after forest clearing and burning with the associated loss of topsoil organic matter and surface exposure with erosive precipitation (McIntyre, 1958a, b; Lal, 1988; Deuchars et al., 1999; Colloff et al., 2010; Bonell et al., 2010). Natural forest regrowth on degraded pasture or planting trees followed by uninterrupted plantation development can be expected to gradually improve the soil water intake capacity again through the steady incorporation of organic matter, soil faunal and insect burrowing activity, and root turnover (Gilmour et al., 1987; Bonell, 2005; Ilstedt et al., 2007; Bonell et al., 2010; Colloff et al., 2010; Hassler et al., 2011; Perkins et al., 2012). Conversely, impervious footpaths, yards and roads will remain runoff-producing features in post-forest landscapes (Ziegler et al., 2004; Rijsdijk et al., 2007) as well as in managed (forest) plantation areas (La Marche and Lettenmaier, 2001; Ziegler et al., 2007; Liu et al., 2009). Likewise, the surface hydraulic conductivity of the intensively used pine forest showed little improvement even 25 years after the trees were planted (Fig. 3). Clearly, the continued human access, grazing and collection of forest products (notably litter from the forest floor to be used for animal bedding and composting; Singh and Sundriyal, 2009; Joshi and Negi, 2011) is having a profound negative effect on the stand’s hydrological functioning (cf. Ghimire et al., 2013, 2014a). Thus, the general expectation of restored surface and near-surface $K_{fs}$ with time after reforestation (cf. Gilmour et al., 1987; Ilstedt et al., 2007) is in need of modification under the conditions of high anthropogenic pressure that appear to be the rule rather than the exception in the Middle Mountain zone (Singh et al., 1984; Mahat et al., 1987; Singh and Sundriyal, 2009; Joshi and Negi, 2011) despite claims to the contrary (HURDEC Nepal and Hobley, 2012). Indeed, if the potential benefits of reforestation such as enhanced infiltration, and therefore possibly improved replenishment of soil water and groundwater reserves are to be realised, then a balance will need to be struck between the continued usage of the forests by uplanders whose livelihoods are at stake and sustained forest hydrological functioning (Ghimire et al., 2014a). Naturally, this holds for many other densely populated tropical uplands as well (e.g. Ding et al., 1992; Van Noordwijk et al., 2001; Forsyth and Walker, 2008; Van Noordwijk and Leimona, 2010).
4.2 Trade-off between changes in vegetation water use and surface infiltration after reforestation

The infiltration trade-off hypothesis states that the ultimate hydrological effect of reforestation in terms of site water yield is determined by the net balance between increases in soil water reserves afforded by improved soil infiltration versus decreases caused by the higher plant water uptake (Bruijnzeel, 1986, 1989). In the absence of direct published evidence of improved dry season flows after reforestation (Jackson et al., 2005; Farley et al., 2005) at the time, Scott et al. (2005) discussed a number of tropical studies that had observed marked reductions in stormflow production at the hillslope (e.g. Zhang et al., 2004; Chandler and Walter, 1998) or small-basin scale (e.g. Zhou et al., 2002) after reforesting severely degraded land. They concluded that in a number of cases the increases in water retention should be more than enough to compensate the estimated corresponding increases in forest water use (not measured). It is unfortunate that the catchments involved did not sustain perennial flows and thus the presumed net positive effect of forestation on dry season flows could not be confirmed (Scott et al., 2005; cf. Chandler, 2006). Nevertheless, recently published evidence from southern China (Zhou et al., 2010), South Korea (Choi and Kim, 2013) and southwestern India (Krishnaswamy et al., 2012, 2013) strongly suggests a net positive outcome of the infiltration trade-off mechanism is possible as long as the initial situation is sufficiently degraded and the site receives ample rainfall (cf. Bruijnzeel et al., 2013).

Such experimental catchment studies usually comprise measurement of the change in streamflow following reforestation but generally lack detailed supporting process-based observations within the catchment undergoing the change (Farley et al., 2005; Scott et al., 2005). As such, the present process-based work which integrated the dominant hydrological processes (notably evaporation, infiltration and runoff generation) to quantify the net hydrological impact of reforestation is a first (cf. Chandler, 2006; Bonell et al., 2010; Krishnaswamy et al., 2013). Comparing the hydrological behaviour of the three contrasting land-cover types studied here (degraded pasture, mature near-undisturbed broadleaved forest, and a heavily used mature pine plantation) within the context of the infiltration trade-off hypothesis showed that planting pines increased vegetation water use relative to the pastures situation by ∼350 mm year⁻¹ (Table 1). On balance, the limited amount of extra infiltration afforded by the pine trees (∼90 mm year⁻¹) is clearly insufficient to compensate the much higher water use of the pines, giving a net negative balance of 260 mm year⁻¹ (Table 2, Fig. 4). Pertinently, the net effect would still have been negative (by ∼120 mm year⁻¹) even if all rainfall would have been accommodated by the pine forest soil through better forest and soil management promoting infiltration (cf. Wiersum, 1985). As such, the observed decline in dry season flows following reforestation in the study area (República, 2012) is likely to primarily reflect the higher water use of the pines (Tables 1, 2; Fig. 5).

If the degraded pasture were to revert to natural forest instead (with an estimated annual ET of 525 mm and very limited overland flow production) the ultimate effect on dry season flows would be expected to be near neutral as the approximate gain in infiltration (∼285 mm year⁻¹) and the extra evaporative loss (∼300 mm year⁻¹) are very similar (Table 2). Effects might be more negative in case the water use of the young regenerating broadleaved forest turned out to be enhanced compared to old-growth forest as found for lowland tropical and warm temperate forests (Vertessy et al., 2001; Giambelluca, 2002).

Although the present finding of a slightly higher ET (∼10%; Table 1) for planted forest compared to natural broadleaved forest is not going to have major hydrological consequences on an annual basis, the much higher water use of the pines during the dry season (Table 1, Fig. 1) is likely to result in a corresponding reduction in dry season water yield upon converting natural broadleaf forest to pine plantations (Fig. 5), especially during the more vigorous early growth stage of the pines (Bruijnzeel, 1997; Scott and Prinsloo, 2008; Alvarado-Barrientos, 2013). The present results further illustrate that the conditions found in the nearly undisturbed natural broadleaved forest and in similarly well-maintained forests elsewhere in the Himalaya (Pathak et al., 1984; Gerrard and Gardner, 2002) will encourage the replen-

Figure 5. Conceptual diagram of the effect of land-cover transformation on annual total and dry season flows in the study area as well as other comparable regions with similar land-cover transformations.
ishment of soil water and groundwater reserves through vertical percolation (geology permitting) more than in any other land-cover type studied here (Fig. 5; cf. Choi and Kim, 2013; Krishnaswamy et al., 2013) and thus better sustain baseflows during the long dry season (Hessel et al., 2007; Tiwari et al., 2011). The importance of the latter in the water-scarce Middle Mountain zone can hardly be overemphasised (Merz et al., 2003; Schreier et al., 2006; Bandyopadhyay, 2013).

4.3 Regional implications

The Himalayan river basins are home to about 1.3 billion people and supply water, food and energy to more than 3 billion people in total (Bandyopadhyay, 2013). Thus, large-scale changes in Himalayan land use and hydrology will have important regional consequences. For example, substantial decreases in dry season flows following advanced surface degradation (Bartarya, 1989; Madduma Bandara, 1997) or large-scale reforestation (cf. Trimble et al., 1987; Zhou et al., 2010) would affect the availability of water for millions of people, both those depending directly on agriculture for their livelihoods and downstream city dwellers. Therefore, large-scale reforestation campaigns and the subsequent use of the planted forests must be based on a sound assessment of what is to be expected hydrologically (Peña-Arancibia et al., 2012; Van Dijk et al., 2012) and meteorologically (Ellison et al., 2011). Precipitation fluctuations in Nepal and northern India have been shown to be strongly influenced by surface temperatures in the Indian Ocean and southwestern Pacific, with dry years coinciding mostly with ENSO (El Niño–Southern Oscillation) events and wet years with La Niña events (Shrestha et al., 2000; Yadav, 2009; Varikoden et al., 2014). Therefore, the influence (if any) of increased forest cover on rainfall in this strongly seasonal environment remains to be ascertained (Basistha et al., 2009). Although continued global warming is predicted to ultimately lead to an increase in precipitation in the Himalayas, such predictions are subject to major uncertainty with respect to the inclusion of aerosol effects and large-scale irrigation in the adjacent plains (Craig Collier and Zhang, 2009; Mathison et al., 2012; Kumar et al., 2013).

The presently observed negative hydrological effect of an apparently long-term trend of gradual forest degradation in the Nepalese Middle Mountain zone goes against the optimistic notion regarding the overall improved quality of Lesser Himalayan forests expressed by HURDEC Nepal and Hobley (2012). However, there is reason to believe that the situation of over-intensive use of forests and the correspondingly poor soil hydrological functioning are a rather more widespread phenomenon in Nepal’s Lesser Himalaya. For example, Gerrard and Gardner (2002) reported very high overland flow occurrence in degraded (broadleaved) forests in the Likhu Khola catchment north of Kathmandu, whereas Tiwari et al. (2009) and Wester (2013) recently presented similar evidence for community-managed forests further west in Nepal. Although process-based hydrological evidence to this effect from the Indian Himalaya is scarce (Negi, 2002; Tiwari et al., 2011; Tyagi et al., 2013) the continued overexploitation of its forest resources is well-documented (Singh et al., 1984; Singh and Sundriyal, 2009; Joshi and Negi, 2011). Such situations may significantly reduce the recharge of shallow groundwater reserves during the monsoon season, thereby potentially decreasing regional dry season flows (Bartarya, 1989; cf. Andermann et al., 2012).

A key message of the present work thus is the need to protect the remaining natural forests in headwater areas throughout the Middle Mountain zone. The present findings further highlight the need for some form of protection of reforested areas that will enable the forest soils to realise the enhanced infiltration/percolation benefits envisaged at the time of planting. Alternative sources of energy to replace fuelwood (e.g. biogas) may take off some of the pressure on the forests (cf. Schreier et al., 2006). Continued degradation of the remaining old-growth forests and planted forests that are now reaching maturity is likely to cause further increases in overland flow production during the monsoon season due to the corresponding decline in infiltration opportunities (Ghimire et al., 2014a). This may, in turn, have a further negative effect on already declining dry season flows and will cause increased hardship to the rural populace (Merz et al., 2003; Schreier et al., 2006). Finally, and most importantly, the present results point to the need for balancing the societal and hydrological functions of forests (both planted and natural) in densely populated uplands. Like elsewhere in Asia (e.g. Tomich et al., 2004; Hairiah et al., 2006), agroforests appear to represent a viable alternative that is on the increase in Nepal (Schreier et al., 2006; Gilmour and Shah, 2012). Not only do they contain a variety of tree and crop species serving a range of uses as opposed to the monospecific character of most planted forests but agroforests are also likely to consume less water (e.g. Wallace et al., 2005) while minimising surface runoff and erosion, thereby maintaining adequate levels of rainfall infiltration (Wiersum, 1984; cf. Hairiah et al., 2006).

Acknowledgements. We dedicate this work to our co-author, friend and colleague Mike Bonell who passed away during the revision stage of the paper. This study was supported financially by the Faculty of Earth and Life Sciences of the VU University Amsterdam (FALW–VUA) and by the Faculty of Geo-Information Science and Earth Observation (ITC–UT) of the University of Twente, Enschede, the Netherlands. Additional financial support was also received from the Royal Society, UK, through the University of Dundee. Neil Coles, Centre for Ecohydrology at the University of Western Australia, is also thanked for his loan of the disc permeameters and support in the associated logistics in the early stages of the field campaign. We acknowledge the indispensable help in the field received from Paras Poudel, Suraj Karki, Sudish Lal Maskey, Umesh Karki, Laxman Baniya, Khadga Bahadur Kharel, Dawa Lama and Kapil Gyawali. We especially would like to thank Pruna Bahadur Magar and his family for their hospitality and support during the field campaign. Enrico Balugani
