Abstract. We present a regional assessment of the spatiotemporal trends in several hydro-climate variables from 1979 to 2010 in Turkey, one of the countries of the eastern Mediterranean vulnerable to climate change, using the two reanalysis products of the ECMWF: ERA-Interim and ERA-Interim/Land. The trend analysis revealed that an average warming of 1.26 °C [0.8–1.8] occurred in Turkey from 1979 to 2010, with high confidence intervals (95–99 %, mostly). Geographically, the largest warming (up to 1.8 °C) occurred in the western coastal areas next to the Aegean Sea and in the southeastern regions. The air temperature trends were generally confirmed by the in situ data from about 100 weather stations around the country, though in situ data indicated slightly higher trends ranging from 1 to 2.5 °C. With respect to the regional trends in hydrological variables, ERA-Interim and ERA-Interim/Land revealed quite different pictures: the ERA-Interim dataset indicated that there have been significant decreasing trends of precipitation, snow water equivalent (SWE) and runoff in some parts of inner/southeastern Anatolia (a total decrease of up to 250 mm in the upstream of the Euphrates, Kizilirmak and Seyhan basins), while ERA-Interim/Land showed no or minor trends in the same areas. Based on the extensive comparisons with precipitation and SWE gauge data, we can suggest that the hydrological trends shown by the ERA-Interim/Land dataset, which is said to be a model improvement, are relatively closer to the observations. From the hydrological trends revealed by the ERA-Interim/Land dataset, we can conclude that, despite the strong warming trends over Turkey from 1979 to 2010, there have been no widespread and strong hydrological trends for the same period throughout the country. In this regard, we can suggest that the impacts of global warming on the water cycle are not straightforward, especially at the regional scale, and future climate simulations indicating considerable reductions in precipitation along with the significant increases in temperatures throughout the Mediterranean and the Middle East by the end of the twenty-first century need to be dealt with cautiously.

1 Introduction

The future climate simulations show that the Mediterranean region is one of the most vulnerable zones in the world. The climate models consistently predict that Mediterranean basin will be affected adversely by climate change in the future (Giorgi and Lionello, 2008; Lelieveld et al., 2012; Ozturk et al., 2014; Önlö et al., 2014; Önlö and Semazzi, 2009; Türkeş et al., 2011), while IPCC reports (2007, 2014) indicating significant increases in temperatures besides considerable reductions in precipitation throughout Mediterranean and the Middle East by the end of the twenty-first century. Observational records and climate projections provide abundant evidence that freshwater resources are vulnerable and have the potential to be strongly impacted by climate change, with wide-ranging consequences for human societies and ecosystems (Yucel et al., 2014). Milly et al. (2005) report 10–30 % reductions in runoff in the Middle East by the year 2050.

Apart from the future simulations, several studies show that the climate and water cycle of the Mediterranean and the Middle East have already undergone significant changes in the recent decades, whether due to climate change and/or direct human influences. Using observations from the Gravity Recovery and Climate Experiment (GRACE) satellite mis-
sion, Voss et al. (2013) indicated an alarming rate of decrease in total water storage in the northern-central Middle East from 2003 to 2009. Yucel et al. (2014) investigated the regional trends in hydroclimatic variables in eastern Anatolia, Turkey, between 1970 and 2010 based on the streamflow and meteorological point measurements. The seasonal snowmelt runoff in the mountainous basins of eastern Turkey has experienced changes over the past several decades (Sen et al., 2011; Sönmez et al., 2014). Sen et al. (2011) indicate that streamflow timings of the Euphrates and Tigris rivers shifted to the earlier days between two consecutive 17-year periods (i.e., 1972–1988 and 1990–2006).

Detection of trends and their significance with confidence generally requires consistent and long-term records of variables considered, especially in the case of detecting climate-change-driven trends (Gokmen et al., 2013a). As stated by Leroy et al. (2008), it is obvious that the longer the time series, the easier it should be to distinguish a trend from natural variability (and measurement uncertainty), because shorter periods of record generally have small signal-to-noise (S/N) ratios (Allen et al., 1994). Based on a hypothetical data set with certain statistical characteristics, Leroy et al. (2008) determined the minimum detection time as about 33 years for detecting a global warming signal of 0.2 K decade$^{-1}$. Similarly, assessing the trend consistency over a range of timescales (from 10 to 32 years), Santer et al. (2011) state that multi-decadal records are required to identify the human effect on the climate variables (e.g., temperature) with high statistical confidence.

The time series of temperature data from meteorological stations are widely used to assess the historical trends; however, as highlighted by Sen et al. (2011), point measurements of temperature come with important shortcomings such as inadequate representation of mountainous areas and contamination by urban heat island effects, as most stations are located in cities (e.g., Ezber et al., 2007).

Reanalysis products provide invaluable temporally and spatially continuous information on various atmospheric variables ranging from near-surface temperature, wind and solar radiation components to hydrological parameters including precipitation, evapotranspiration and runoff. Besides the weather forecast services, one of the primary aims of the reanalysis product by the European Centre for Medium-Range Weather Forecasts (ECMWF) is stated to construct a long-term homogeneous record of the atmosphere, which is achieved by systematic assessment, inter-calibration, and integration of the observational record in the context of physical models (Dee et al., 2011). Simmons et al. (2010) show that surface temperature and humidity trends from 45-year ECMWF Re-Analysis (ERA-40; Uppala et al., 2005) and ERA-Interim are in excellent agreement with estimates obtained from climatological land station data from the Hadley Centre. Balsamo et al. (2010) evaluated the suitability of ERA-Interim precipitation estimates for land applications at various timescales from daily to annual over the conterminous USA. Decker et al. (2012) showed that the land surface evaporation of ERA-Interim compared favorably with the flux tower observations and with other reanalysis. The results of the studies based on reanalysis were also used in the 5th Assessment Report (IPCC, 2014), which state that adequacy of trend detection using reanalysis data depends on the variable under consideration, the time period and the region of interest. For example, surface air temperature and humidity trends over land in the ERA-Interim reanalysis compare well with observations (Simmons et al., 2010), but polar tropospheric temperature trends in ERA-40 disagree with trends derived from radiosonde and satellite observations (Bitz and Fu, 2008; Grant et al., 2008; Graversen et al., 2008; Screen and Simmonds, 2011). Recently, ECMWF has introduced a new product, namely ERA-Interim/Land, which incorporates the up-to-date land model developments by combining near-surface meteorological fields from ERA-Interim with the latest version of the HTesSlel land surface model (Hydrological Tiled ECMWF Scheme for Surface Exchanges over Land), which is an extension of the TESSEL scheme (van den Hurk et al., 2000) used in ERA-Interim. Balsamo et al. (2015) state the added-value components of ERA-Interim/Land as soil, snow and vegetation description upgrades, as well as a bias correction of the ERA-Interim monthly accumulated precipitation based on GPCP v2.1.

In this study, we utilized reanalysis datasets of ECMWF (both ERA-Interim and ERA-Interim/Land) to analyze the spatiotemporal trends in several hydro-climate variables (i.e., near-surface air temperature, precipitation, snow water equivalent, runoff and evapotranspiration) at the regional scale. More specifically, this study aims at

- determining the significance and magnitude of the hydro-climatic trends over the last decades (from 1979 to 2010) in a spatially distributed manner,

- and comparing the trends detected by the ERA-Interim and ERA-Interim/Land datasets with in situ data (where available), in Turkey, one of the countries of the eastern Mediterranean vulnerable to climate change. The Anatolian peninsula not only shows high gradients of topography (from sea level to above 5000 m) and hydro-climate (yearly average total precipitation ranging from around 400 mm in the semi-arid inner Anatolia plateau to above 2000 mm in the humid northeastern Black Sea coast), but has also been undergoing severe human interferences through land-use changes due to deforestation, conversion to agricultural lands, expansion of urban lands, and building of dams, among others.

2 Materials and methods

2.1 The study area

Turkey is situated in Anatolia (97%) and the Balkans (3%), bordered by the Black Sea in the north, and the Aegean Sea and the Mediterranean Sea in the west and the south (Fig. 1a). Due to its complex terrain and the long land–sea boundary interactions, the climate of the country varies from the Mediterranean (in the coastal areas in the west and south) to the continental climate in the inner Anatolian plateau, while the Black Sea coast in the north is humid due to the orographic effect of the steep topography. As shown by the long-term average of the precipitation (P) to evapotranspiration (ET) ratio in Fig. 1b, except for the humid northeastern region by the Black Sea, most of the study area has relatively semi-arid conditions, with a P / ET ratio of less than 1. Annual precipitation is relatively low (around 400 mm) in the semi-arid central Anatolia plateau; it varies from 600 to 1300 mm
in the Aegean and Mediterranean coasts, while the eastern coast of the Black Sea receives the greatest amount, with over 2000 mm annual rainfall (Bozkurt and Sen, 2011).

2.2 Methods

The time series of temperature and all the hydrologic variables were analyzed using the Mann–Kendall non-parametric test for detecting the significance and the direction of the trend. Mann (1945) originally used this test and Kendall (1975) subsequently derived the test statistic distribution. The Mann–Kendall test has two parameters that are of importance for trend detection: the significance level that indicates the trend’s strength (p value) and the slope magnitude (Kendall’s tau) estimate that indicates the direction as well as the magnitude of the trend. After detecting the significance level and the direction of trends by the Mann–Kendall test, the magnitudes (slopes) of trends were determined using linear models.

In order to apply the trend analysis in a spatially distributed manner, the Mann–Kendall test was applied using the R software and the Kendall package for R (http://cran.r-project.org/web/packages/Kendall/Kendall.pdf).

2.3 Data

In this study, we used two different reanalysis products by ECMWF: ERA-Interim and ERA-Interim/Land (which will be referred to as Interim/Land from here on). Table 1 provides a summary of the variables that were considered for the trend analyses.

The ERA-Interim atmospheric reanalysis is built upon a consistent assimilation of an extensive set of observations (typically tens of millions daily) distributed worldwide (from satellite remote sensing, in situ, radio sounding, profilers, etc). Besides ERA-Interim, we also used a new product by ECMWF, namely Interim/Land. Balsamo et al. (2015) indicate that Interim/Land is produced by combining near-surface meteorological fields from ERA-Interim with the latest version of the HTESSEL land surface model. HTESSEL is an extension of the TESSEL scheme (van den Hurk et al., 2000) used in ERA-Interim. HTESSEL includes an improved soil hydrology (Balsamo et al., 2009), a new snow scheme (Dutra et al., 2010), a multiyear satellite-based vegetation climatology (Boussetta et al., 2013), and revised bare soil evaporation (Balsamo et al., 2011; Albergel et al., 2012).

The original ERA-Interim is produced at T255 spectral resolution (about 80 km) and covers the period from January 1979 to the present, while Interim/Land covers the period between 1979 and 2010. To allow comparison, we used 1979–2010 as the study period for both datasets. Also, we used a spatially rescaled version (0.25° × 0.25°) of the datasets as provided by ECMWF.

In addition to the reanalysis datasets, in situ data of air temperature from nearly 100 meteo-stations (unpublished data from the Turkish Meteorological Service), precipitation from nearly 80 rain gauges (unpublished data from the Turkish Meteorological Service) and snow measurements from six stations (unpublished data from State Hydraulic Works, DSI) were used for necessary comparisons. The details of calculating snow water equivalent (SWE) from in situ snow measurements are described in Gokmen et al. (2013b).

3 Hydro-climate trends

3.1 Air temperature

As the Interim/Land product mainly focused on model updates related to the hydrological variables and did not include an air temperature output, here only the results from ERA-Interim are presented, together with the in situ data distributed over the country. Figure 2a shows that, apart from the eastern region, Turkey has experienced significant increases in air temperature from 1979 to 2010, whose distribution is generally confirmed by the trends detected for the in situ measurements. The significance level for the increasing temperature trends was high (p < 0.01–0.05) in most of the country. The non-significant trend region in eastern Anatolia corresponds to the relatively high-altitude region of the country with complex topography (Fig. 1a).

During the 32-year study period, the total temperature increase indicated by ERA-Interim generally ranged between 0.8° (mostly in the eastern and northeastern regions) and 1.8°...
Figure 3. (a) The comparison of the average yearly temperature between (all) the stations (shown in Fig. 2) and the corresponding grids from the ERA-Interim dataset. (b) The comparison of the total 32-year increase in temperatures by the meteo-stations and the corresponding grids from the ERA-Interim with respect to elevation.

(western coastal areas and in the southeastern regions), as shown in Fig. 2b. While the in situ data from weather stations generally agree with the distribution of the total warming, the increase was slightly higher, ranging from 1 to 2.5°C.

Showing the comparison of the yearly average air temperature of (all) the stations with the average of the corresponding grids from ERA-Interim, Fig. 3a indicates systematically higher temperatures by in situ measurements (about 1.8°C), but a similar rate of increase is confirmed by the slope of the fitted trend lines for both in situ data and ERA-Interim. The higher yearly average temperature of the stations can generally be attributed to the fact that the in situ measurements not only represent the local environment at lower altitudes inside a grid (as the stations are usually installed at lower altitudes for ease of maintenance) compared to the 80 km original resolution of ERA-Interim, but that they are also more prone to urban heating effects. Assessing the total temperature increases by the meteo-stations and the corresponding ERA-Interim grids with respect to elevation, Fig. 3b shows that the temperature increases are higher in the lowlands and relatively lower at the higher altitudes, as indicated by both the ERA-Interim and meteo-stations, apart from the generally higher total increase by the in situ data.

3.2 Total precipitation

In ECMWF Reanalysis, total precipitation, which includes rain and snow, is estimated as the sum of convective precipitation and large-scale precipitation. With respect to total precipitation trends, ERA-Interim (Fig. 4a) and Interim/Land (Fig. 4b) reveal quite different pictures: except for the western part and some of the southeastern regions, the significance and direction of the precipitation trends are indicated as highly different by ERA-Interim and Interim/Land in most of the study area. When these trends are compared with the in situ measurements, the trends of the in situ data are relatively closer to the precipitation trends of Interim/Land rather than ERA-Interim. Especially the widely decreasing trends indicated by ERA-Interim in the southern/southeastern and northeastern regions are not confirmed by the non-significant trends indicated by the stations (Fig. 4a). For these regions there is a general agreement between Interim/Land and the stations (Fig. 4b). The only region where ERA-Interim and Interim/Land both indicate significant increasing precipitation trends is the western region, which is confirmed by in situ data, especially in the northwest.

In terms of the magnitude of trends (Fig. 4c and d), while the in situ data indicate a range of 50–150 mm total increase/decrease in precipitation (1979–2010 period) at the significant trend locations (except for a 314 mm increase at Rize station in the northeast), ERA-Interim indicated a total decrease in precipitation of as high as 250 mm in some parts of the southeast and northeast (Fig. 4c), and Interim/Land showed a decrease of up to 120 mm in the southeast and a 50–150 mm total increase in the areas with significant increasing trends.

Considering that Turkey shows strong seasonality and that some trends can be lost when evaluated annually, total precipitation trends were also evaluated at the seasonal scale. For ERA-Interim, the decreasing trends in the southern and southeastern regions are observed in winter, spring and autumn, but the decrease is most widespread and highlighted in spring (Fig. 5). The increasing trend in the west is most widespread in autumn but also partly observed in winter. Similarly in autumn (and partly in winter), the Interim/Land dataset also indicates a widespread increase in precipitation, especially in the west/northwest, in parts of inner Anatolia and some areas in the northeast. For Interim/Land, the decrease in precipitation in the southeastern region is also observed in winter, spring and autumn, but it is relatively local and quantitatively less compared to ERA-Interim. As the stations’ data were only available on a yearly scale, a seasonal comparison with the in situ data could not be carried out.
3.3 Snow water equivalent

Runoff from snowmelt-dominated basins in the mountainous and semi-arid regions of eastern Turkey accounts for 60–70% of the total annual runoff for the region (DSI, 2009). Therefore, inter-annual changes in snowfall quantities are especially important for the mountainous regions in eastern Anatolia. According to the ERA-Interim dataset (Fig. 7a and c), there have been highly significant decreasing trends ($p < 0.01$) of snow water equivalent (SWE) in the upstream parts of the Euphrates, Kızılırmak and Seyhan basins: up to 250 mm decrease in total for the 32-year study period. Apart from the decreasing trends, the ERA-Interim dataset revealed significant increasing trends of SWE in southwestern Turkey and in various regions along the Black Sea coast. On the other hand, the ERA-Interim/Land dataset (Fig. 7b and d), which is said to be a model improvement integrating a new snow scheme by Dutra et al. (2010), indicated no considerable trends with respect to SWE throughout the country. Indeed, a comparison with data from six SWE gauge stations shows that SWE trends from the Interim/Land dataset are quite similar to the in situ data (Fig. 8): both indicate no significant trends despite the differences in terms of SWE magnitudes. Although station no. 6 (and Interim/Land) shows some in-

creasing trend (Fig. 8), the time series is too short for trend detection. In Fig. 8, the ERA-Interim dataset generally shows significant decreasing trends of SWE for the same locations.

3.4 Evapotranspiration

With respect to evapotranspiration (ET) trends, while both ERA-Interim and ERA-Interim/Land show similar trends over the Mediterranean, Aegean and Black seas and some areas in the southeast, the two datasets indicate rather contradicting trends over the land along the Anatolian peninsula (Fig. 9a and b). Such a general pattern of consistent ET trends over the sea and non-consistent trends over the land between ERA-Interim and ERA-Interim/Land can possibly be attributed to the different controlling mechanisms of ET (Seneviratne et al., 2010): over the sea, ET is mainly energy-limited (i.e., temperature and incoming radiation), while over the land, ET is generally water-limited (i.e., precipitation and soil moisture) in semi-arid regions and energy-limited in humid regions. Therefore, a clearly increasing trend of air temperature over the entire study area (Fig. 2) mainly explains the increasing trend of ET over the sea as detected by both datasets. On the other hand, considering most of the study area has semi-arid conditions (Fig. 1b) and precipitation becomes more controlling than air temperature over semi-arid lands, the contradicting trends of precipitation shown in Fig. 4 are reflected similarly for the ET trends detected by ERA-Interim and Interim/Land along the Anatolian peninsula from west to east (Fig. 9a and b). In terms of magnitude of ET trends (Fig. 9c and d), both datasets indicate that
the highest increasing ET trends (up to 250 mm in total) occurred over the Mediterranean coast in the southwest, where the highest rates of temperature increase were experienced too, as shown in Fig. 2b.

### 3.5 Runoff

Similar to precipitation and SWE trends, runoff trends were revealed differently by two reanalysis datasets: while ERA-Interim revealed significantly decreasing trends of runoff in certain regions of Anatolia (Fig. 10a), Interim/Land indicated only minor increasing trends in some limited areas in central Anatolia and the southeastern regions. In terms of magnitude, ERA-Interim indicated a total decrease of as high as 250 mm in the upstream of the Euphrates, Kizilirmak and Seyhan basins (Fig. 10c), but the quantity of increase/decrease indicated by Interim/Land was generally lower than 100 mm for the 32-year period (Fig. 10d). Although no comparison with in situ or other independent data was carried out, a correlation analysis confirmed that there is a highly significant positive correlation between runoff and precipitation for both reanalysis datasets (Fig. 11). From such high correlations we can deduce that the validations of total precipitation with in

**Figure 8.** Plots 1–6 indicate the comparison of the yearly SWE from the snow gauges with the corresponding grids from ERA-Interim and Interim/Land. While the time series of SWE covered the whole study period for stations 1–3, the station data were available for a much shorter period for 4–6. The locations of the stations are shown in Fig. 7a, b.
Figure 9. The distribution of the presence and the direction of evapotranspiration (ET) trends by (a) ERA-Interim and (b) Interim/Land. The magnitudes of 32-year total ET trends by (c) ERA-Interim and (d) Interim/Land. The polygons in (c) and (d) delineate the 26 water basins in the country.

Figure 10. The distribution of the presence and the direction of runoff trends by (a) ERA-Interim and (b) Interim/Land. The magnitudes of 32-year total runoff trends by (c) ERA-Interim and (d) Interim/Land. The polygons in (c) and (d) delineate the 26 water basins in the country.

situ data can be assumed to be valid for runoff data as well. Indeed, analyzing the streamflow trends in eastern Anatolia, Yucel et al. (2014) found that only 2 of the streamflow stations out of 15 showed evidence of significant change (both decreasing trends) in the total annual river discharges between 1970 and 2010.

4 Discussion and conclusions

In this study, we assessed the spatiotemporal trends in several hydro-climate variables from 1979 to 2010 in Turkey, one of the countries of the eastern Mediterranean vulnerable to climate change, using the two reanalysis products of ECMWF: ERA-Interim and Interim/Land.

With respect to air temperature, the ERA-Interim reanalysis dataset revealed highly significant increasing trends (95–99% confidence intervals) with an average warming of 1.26 °C [0.8–1.8] in Turkey from 1979 to 2010 (Fig. 2a and b), which is relatively high compared to the globally averaged increase of 0.72 °C over the period 1951–2012 according to the 5th Assessment Report (IPCC, 2014). The distribution of the significance and the magnitude of the air temperature trends were generally confirmed by the in situ data from about 100 weather stations around the country, though in situ data indicated slightly higher trends ranging from 1 to 2.5°. The increased exposure of the stations to the urban heat effect during the 32-year study period possibly explains the higher warming detected by the meteo-stations.
showed none or minor decreasing trends in the southeast/northeastern Anatolia. Interim/Land indicated significant decreasing trends of precipitation in quite different pictures: while the ERA-Interim dataset indicated warming in eastern Anatolia.

The possible explanations for the lower and/or non-significant trends detected by ERA-Interim and Interim/Land along the coast are among snow–albedo feedbacks and the lower contribution of the direct land-use changes to the temperature increase are among the possible explanations for the lower and/or non-significant warming in eastern Anatolia.

Geographically, the highest warming (up to 1.8°C) occurred in the western coastal areas next to the Aegean Sea and in the northeastern parts (Fig. 4). When these trends are compared with the rain-gauge data, the trends of Interim/Land are relatively closer to the precipitation trends of in situ data, confirming the minor decreasing precipitation trends in the southeast and some increasing trends in the northeast. The only region where ERA-Interim and Interim/Land both indicate significant increasing precipitation trends is the western region, which is also confirmed by in situ data, especially in the northwest.

Similar to precipitation, SWE and runoff trends were revealed differently by the two reanalysis datasets: while ERA-Interim indicated significant and highly decreasing trends of SWE and runoff in the upstream of the Euphrates, Seyhan and Kizilirmak basins (Figs. 7c and 10c), Interim/Land showed no or only minor trends in some limited areas in central Anatolia and the southeastern regions (Figs. 7d and 10d). A comparison with data from six SWE gauge stations showed that SWE trends from the Interim/Land dataset are quite similar to the in situ data (Fig. 8); both indicate no significant trends despite the differences in terms of SWE magnitudes. Although Sönmez et al. (2014) indicated dominantly negative trends for the snow cover over Turkey, the study period was relatively short (2004–2012) for a reliable trend analysis. Although the validation of the runoff trends could not be carried out with in situ data, a correlation analysis showed that runoff and precipitation are positively correlated extensively for both reanalysis datasets (Fig. 11), implying the validation of precipitation would be valid for runoff as well. Indeed, assessing the river discharge trends in the mountainous eastern region, Yucel et al. (2014) also indicated that there are generally no statistically meaningful trends in the river discharges (only 2 of the 15 stations showed evidence of a decreasing trend) over the study period (1970–2010), while the timing of spring streamflow significantly shifted earlier in the year.

Among the hydrological variables, the only consistent hydrological trend detected by both datasets was the increase in evapotranspiration over the Mediterranean and Black seas, whose magnitude was especially considerable (up to 250 mm in total) over the Mediterranean coast in southwestern Turkey (Fig. 9c and d). Combined with the strong warming and the increasing precipitation trend in the same region, we can suggest that the warming in the southwestern Mediterranean is reflected as increased precipitation (especially in autumn, Figs. 5 and 6) in the western coastal areas through intensified evapotranspiration and changes in the type (i.e., snow becomes rain) and intensity of precipitation. However, such regional temperature–evapotranspiration–precipitation feedbacks are rather absent in the majority of the inland Anatolian peninsula: considering most of the study area has semi-arid conditions (Fig. 1b) and the precipitation becomes a more controlling factor for evapotranspiration than air temperature over semi-arid lands, the contradicting trends of precipitation shown in Figures 4a and 4b are reflected similarly for the ET trends detected by ERA-Interim and Interim/Land along the

![Figure 11](image-url)
Anatolian peninsula from west to east (Fig. 9a and b). Although there are global ET datasets available (e.g., Chen et al., 2014, among others), a comparison with these independent ET datasets could not be carried out because the temporal coverage of freely available datasets does not match with the period of this study.

Although it should be noted that verification of the grid-based reanalysis data with the point-based station data prone to certain errors as stations may not be representative of a large area, especially in mountainous complex terrains, we can still suggest that, based on the extended comparisons with precipitation and SWE gauge data, the hydrological trends from 1979 to 2010 in Turkey revealed by the Interim/Land dataset are closer to the observations. Indeed, compared to ERA-Interim, Interim/Land is said to be a model improvement that includes an improved soil hydrology (Balsamo et al., 2009), a new snow scheme (Dutra et al., 2010), a multiyear satellite-based vegetation climatology (Boussetta et al., 2013), and a revised bare soil evaporation (Balsamo et al., 2011; Albergel et al., 2012).

Finally, considering that the Interim/Land dataset revealed no clear and strong hydrological trends over Turkey from 1979 to 2010 despite the strong warming (ERA-Interim) for the same period throughout the country, we can suggest that the impacts of global warming on the water cycle are not straightforward, especially at the regional scale. In this regard, the sections of the IPCC reports (2007, 2014) indicating considerable reductions in precipitation along with the significant increases in temperatures throughout the Mediterranean and the Middle East by the end of the twenty-first century need to be dealt with cautiously. Indeed, the 5th Assessment Report also declares low confidence for detecting long-term positive or negative trends in the hydrological cycle over different latitudinal zones due to data quality, data completeness or disagreement amongst available estimates.

5 Data availability

The Reanalysis data sets used in this study are freely available and can be downloaded from the ECMWF’s data portal: http://www.ecmwf.int/en/research/climate-reanalysis/browse-reanalysis-datasets.

The in situ data used for validation can be accessed and downloaded from: https://drive.google.com/folderview?id=0BwahP5fV3XOFd2RGTVBELUh3Ync&usp=sharing.

Acknowledgements. I thank Faize Saris from Canakkale 18 Mart University for providing the temperature data from weather stations distributed all over the country.

I also thank Yucel Kaya from the State Hydraulic Works (DSI) for providing the snow observation data.

Finally, I thank to the editor handling the manuscript and the five anonymous reviewers for their constructive comments to improve this paper.
