Abstract. Multiple water sources and the physiographic heterogeneity of glacierized catchments hamper a complete conceptualization of runoff response to meltwater dynamics. In this study, we used environmental tracers (stable isotopes of water and electrical conductivity) to obtain new insight into the hydrology of glacierized catchments, using the Saldur River catchment, Italian Alps, as a pilot site. We analysed the controls on the spatial and temporal patterns of the tracer signature in the main stream, its selected tributaries, shallow groundwater, snowmelt and glacier melt over a 3-year period. We found that stream water electrical conductivity and isotopic composition showed consistent patterns in snowmelt-dominated periods, whereas the streamflow contribution of glacier melt altered the correlations between the two tracers. By applying two- and three-component mixing models, we quantified the seasonally variable proportion of groundwater, snowmelt and glacier melt at different locations along the stream. We provided four model scenarios based on different tracer signatures of the end-members; the highest contributions of snowmelt to streamflow occurred in late spring–early summer and ranged between 70 and 79 %, according to different scenarios, whereas the largest inputs by glacier melt were observed in mid-summer, and ranged between 57 and 69 %. In addition to the identification of the main sources of uncertainty, we demonstrated how a careful sampling design is critical in order to avoid underestimation of the meltwater component in streamflow. The results of this study supported the development of a conceptual model of streamflow response to meltwater dynamics in the Saldur catchment, which is likely valid for other glacierized catchments worldwide.

1 Introduction

Glacierized catchments are highly dynamic systems characterized by large complexity and heterogeneity due to the interplay of several geomorphic, ecological, climatic and hydrological processes. Particularly, the hydrology of glacierized catchments significantly impacts downstream settlements, ecosystems and larger catchments that are directly dependent on water deriving from snowmelt, glacier melt or high-elevation springs (Finger et al., 2013; Engelhardt et al., 2014). Water seasonally melting from snowpack and glacier bodies can constitute a larger contribution to annual streamflow than rain (Cable et al., 2011; Jost et al., 2012), and is widely used, especially in Alpine valleys, for irrigation and hydropower production (Schaeffli et al., 2007; Beniston, 2012). It is therefore pivotal for an effective adoption of water resources strategies to understand the origin of water and to quantify the proportion of snowmelt and glacier melt in streamflow (Finger et al., 2013; Fan et al., 2015). To achieve this goal it is critical to gain a more detailed understanding of the hydrological functioning of glacierized catchments through the analysis of the spatial and temporal variability of water sources and the spatial and seasonal meltwater (snowmelt plus glacier melt) dynamics.
Hydrochemical tracers (e.g. temporary storage of winter–
early spring precipitation in the snowpack and in the glacier
body and their melting during the late spring and summer
to control the variability in solute and isotopic compositions
of stream water (Kendall and McDonnell, 1998). Therefore,
hydrochemical tracers allow for an effective identification
of water sources and their variability within the catchments
and over different seasons, providing essential information
about water partitioning and water dynamics and improving
our understanding of complex hydrology and hydrocli-
natology of the catchment (Rock and Mayer, 2007; Fan et
al., 2015; Xing et al., 2015). Particularly, a few works re-
lied on stable isotopes of water (\(^{2}H\) and \(^{18}O\)) used in
combination with EC to evaluate the role played by meltwater in
the hydrology of glacierized catchments. For instance, some
of these investigations allowed for the separation of stream-
flow into subglacial-, englacial-, melt- and rainfall-derived
components in the South Cascade Glacier, USA (Vaughn
and Fountain, 2005), into components due to monsoon rain-
fell runoff, post-monsoon interflow, winter snowmelt and
groundwater (the latter estimated up to 40 % during summer
and monsoon periods) in the Gangsa River, Himalaya (Ma-
rya et al., 2011), and into snowmelt, ice melt and shallow
groundwater components in Arctic catchments characterized
by a gradient of glacierization (Blæn et al., 2014). Other re-
searchers assessed the possibility to use isotopes and EC as
complementary tracers, in addition to water temperature, to
identify a permafrost-related component in spring water in a
glacierized catchment in the Ortles-Cevedale massif, Italian
Alps (Carturan et al., 2016).

Two recent studies used stable isotopes and EC over a 3-
year period to assess water origin and streamflow contribu-
tors in the glacierized Saldur River catchment, Italian Alps.
Penna et al. (2014) showed a preliminary analysis on the
highly complex EC and isotopic signature of different waters
sampled in the catchment, identifying distinct tracer signals
in snowmelt and glacier melt. These two end-members dom-
ninated the streamflow throughout the late spring and summer,
whereas liquid precipitation played a secondary role, limited
to rare intense rainfall events. They also assessed, without
quantifying it, the switch from snowmelt- to glacier melt-
dominated periods, and estimated that the snowmelt fraction
in groundwater ranged between 21 and 93 %. Engel et
al. (2016) employed two- and three-component mixing mod-
els to quantify the relative contribution of snowmelt, glacier
melt and groundwater to streamflow during seven representa-
tive melt-induced runoff events sampled at high frequency at
two cross sections of the Saldur River. They observed marked
reactions of tracers and streamflow both to melt and rainfall
inputs, identifying hysteretic loops of contrasting directions.
They estimated the maximum contribution of snowmelt dur-
ing June and July events (up to 33 %) and of glacier melt
during the August events (up to 65 %). However, a quantifi-
cation of the variations of streamflow components not only
at the seasonal scale but also at different spatial scales across
the catchment was not performed and a conceptual model of
meltwater dynamics was not presented. Therefore, de-
spite the number of studies that have conducted hydrological
tracer-based investigations in high-elevation mountain catch-
ments, there is still the need to gain a better comprehension of
the factors determining the complex hydrochemical signature
of stream water and groundwater in glacierized catchments.

This research builds on the existing database for the Saldur
River and on the first results presented in Penna et al. (2014)
and Engel et al. (2016) to improve the knowledge of the com-
plex hydrology and the water source dynamics in glacierized
catchments. Specifically, we aim to

- assess the controls on the spatial and temporal vari-
ability of the isotopic composition and EC in the main
stream, tributaries and springs in the Saldur River catch-
ment;
- quantify the proportion of snowmelt and glacier melt in
streamflow at different stream locations and at different
times of the year, as well as the related uncertainty;
- analyse the relation between the tracer signature and
streamflow variability;
- derive a conceptual model of streamflow response to
meltwater dynamics.

2 Study area

The research has been conducted in the upper portion of the
Saldur River catchment, Vinschgau Valley, eastern Italian
Alps (Fig. 1). The catchment size is 61.7 km\(^{2}\) and altitude
ranges between 1632 m a.s.l. at the outlet (46°42′42.37″ N,
10°38′51.41″ E) and 3725 m a.s.l. A glacier lies in the upper
part of the catchment, with an extent of 2.28 km\(^{2}\) in 2013, i.e.
approximately 4 % of the total catchment area (Galos and
Kaser, 2013). The glacier lost 21 % of its area from 2005
to 2013 (Galos and Kaser, 2013). Several glacier-fed and
non-glacier-fed lateral tributaries contribute to the Saldur
River streamflow, and various springs, apparently connected
or not connected to the main stream, can be found on the
valley floor and at the toe of the hillslopes in the mid-
upper part of the catchment. Rocks are metamorphic, mainly
gneisses, mica-gneisses and schists. Land cover changes
with elevation typically varying from Alpine forests (up to
about 2200 m a.s.l.) to shrubs to Alpine grassland, bare soil
and rocks above 2700 m a.s.l. The area is characterized by
a continental climate with an average annual air tempera-
ture of 6.6 °C and precipitation as low as 569 mm yr\(^{-1}\) (at
1570 m a.s.l.), likely increasing up to 800–1000 mm yr\(^{-1}\) in
the upper parts of the catchment. At 3000 m a.s.l., the total
precipitation can be estimated, using the approach of Mair
et al. (2016), to be about 1500 mm. 80 % of which falls as
snow. The hydrological regime is typically nivo-glacial with
minimum streamflow recorded in winter and high flows occurring from late spring to mid-summer, when marked diurnal streamflow cycles occur, related to snowmelt and glacier melt (Mutzner et al., 2015). More detailed information on the study area are reported in Mao et al. (2014) and Penna et al. (2014).

3 Materials and methods

3.1 Hydrological and meteorological measurements

Field measurements were conducted from April 2011 to October 2013. Meteorological data were recorded at 15 min temporal resolution by two stations located at 2332 and 1998 m a.s.l. (Fig. 1a). The stage in the Saldur River was recorded every 10 min by pressure transducers at the catchment outlet and at two river sections labelled lower stream gauge (S3-LSG; 2150 m a.s.l.) and upper stream gauge (S5-USG; 2340 m a.s.l.), which defined two nested subcatchments with an area of 18.6 and 11.2 km$^2$, respectively (Fig. 1a). Streamflow values were obtained by 82 discharge measurements acquired by the salt dilution method during various hydrometric conditions over the three study years. Water level was also continuously measured on a left tributary (T2-SG; 2027 m a.s.l.; Fig. 1b) draining an area of 1.7 km$^2$ but a robust rating curve was not available to derive streamflow.

3.2 Tracer sampling and measurement

Samples analysed for the two tracers were collected from snowmelt, glacier melt, stream water and groundwater. Snowmelt was sampled in late spring–early summer from water dripping from the residual snowpack at different elevations and different locations. Snowmelt was sampled on three occasions in summer 2012 (end of June, beginning and end of July), at elevations roughly between 2150 and 2350 m a.s.l., and on nine occasions in summer 2013 (June, July and August) at elevations roughly between 2150 and 2600 m a.s.l. Glacier melt was sampled from small rivulets flowing on the glacier surface, roughly at 2800 m a.s.l. in July and August 2012, and in July, August and September 2013. Grab stream-water samples were taken approximately monthly at eight locations in the Saldur River (labelled from S1 to S8), at elevations spanning from 1809 m a.s.l. (S1) and 2415 m a.s.l. (S8), and from five tributaries (labelled from T1 to T5), at elevations between 1775 m a.s.l. (T1) to 2415 m a.s.l. (T5; Fig. 1b). Samples at T1 were taken only in 2012, and samples at T3 only in 2011. In 2013 samples were collected monthly during clear days only from the river at four sections (S1, S3-LSG, S5-USG, S8), respectively at the same time of the day on each occasion in order to ensure consistency and comparability between measurements. The representativeness of these samples for the typical melting conditions in the catchment was visually ensured by comparing the hydrographs of the sampled days with the ones of the corresponding months during the three monitored years. No wells are available in the study area.

catchment; thus, spring water was assumed to represent shallow groundwater (Kong and Pang, 2012; Racoviteanu et al., 2013). Four springs (labelled from SPR1 to SPR4) localized near the outlet of USG, between 2334 and 2360 m a.s.l., were sampled monthly during the three study years. On one occasion (17 October 2011) no sample was taken from SPR1 because it was found dry. Additionally, monthly samples were also taken from June to September 2013 from two springs on the left valley hillslope, SPR6 and SPR7 at 2512 and 2336 m a.s.l., respectively (Fig. 1b). A list of all sampling locations with their main characteristics is reported in Penna et al. (2014).

In addition to the monthly sampling, stream water samples were collected at USG and LSG during seven runoff events induced by meltwater in July and August 2011, and June, July and August 2012 and 2013. Samples were collected from 10:00 LT of one day to 10:00 LT (or longer) on the following day at hourly frequency during the day until 22:00 LT, and every 3 h during the night. For those events, two- and three-component mixing models were applied to quantify the fraction of snowmelt and glacier melt in streamflow. Description of the runoff events and hydrograph separation results are reported in Engel et al. (2016). The number of samples collected from the different water sources at the various locations and years used in this study is reported in Table 1.

EC was determined directly in the field by means of a conductivity meter with a precision of ±0.1 µS cm$^{-1}$. The EC meter was routinely calibrated to ensure consistency among the measurements. Grab water samples for isotopic determination were taken by 50 mL HDPE (high-density polyethylene) bottles with two caps and completely filled to avoid head space. Isotopic analysis was carried out by an off-axis integrated cavity output spectrooscope tested for precision, accuracy and memory effect in previous intercomparison studies (Penna et al., 2010, 2012). The observed instrumental precision, considered as the long-term average standard deviation, is 0.5 ‰ for δ$^2$H and 0.08 ‰ for δ$^{18}$O. Isotopic values are presented using the δ notation referred to the SMOW2–SLAP2 scale provided by the International Atomic Energy Agency.

3.3 Two- and three-component mixing models and underlying assumptions

A one-tracer, two-component mixing model (Pinder and Jones, 1969; Sklash and Farvolden, 1979) was used to quantify and separate two streamflow components (groundwater and snowmelt), and a two-tracer, three-component mixing model (Ogunkoya and Jenkins, 1993) was used for three streamflow components (groundwater, snowmelt and glacier melt). Mixing models were applied only to 2013 data because in that year water samples were collected at four locations along the main stream (S1, S3-LSG, S5-USG and S8) at the same time of the day on all sampling occasions. This was critical to ensure comparability of the results, given the high diurnal variability of streamflow and associated isotopic composition and EC, especially during the summer. In addition, results from the application of the two- and three-component mixing models to data collected hourly during seven melt-induced runoff events presented in Engel et al. (2016) were also used in this study for comparison purposes (see Sect. 4.3).

The following simplifying assumptions were made for the application of the mixing models:

- Streamflow at each selected sampling location of the Saldur River was a mixture of two components, viz. groundwater and snowmelt, or three components, viz. groundwater, snowmelt and glacier melt. The influence of precipitation was considered negligible because samples were collected during non-rainy periods, and particularly during warm, clear days when the meltwater input to runoff was remarkable and overwhelmed the possible presence of rain water in streamflow.
– The largest contribution of snowmelt to streamflow was assumed to derive from snow melting at an approximate elevation of 2800 m a.s.l. The elevation band between 2800 and 2850 m a.s.l. was the one with the largest area in the catchment (3.4 km²), where much snow can accumulate, as confirmed by the analysis of snow cover data from Moderate Resolution Imaging Spectroradiometer (MODIS) images (cf. Engel et al., 2016).

The three-component mixing model was based on isotopic and EC data (Maurya et al., 2011; Penna et al., 2015) and first applied to all samples collected in the Saldur River in 2013. When the three-component mixing model yielded inconsistent results, typically in May and June and partially in October, it was inferred that there was no glacier melt component in streamflow; thus, the two-component mixing model was performed to separate the snowmelt from the groundwater component. As a preliminary step, both EC and isotopes were used in the two-component mixing model. The resulting estimates were strongly correlated ($p < 0.01$) but, overall, snowmelt fractions computed for May and June using isotopes were smaller compared to those computed through EC. In agreement with our previous work in the Saldur catchment (Engel et al., 2016), we decided to present EC-based results for the sampling days in May and June because of the large difference between the low EC of the snowmelt end-member and the relatively high EC of the stream that provided lower uncertainties in the estimated fractions compared to isotopes (Genereux, 1998). Conversely, for the sampling day in October, there was a relatively small difference between the EC of the groundwater end-member and the EC of the stream, while the difference in the isotopic signal of the end-members was greater, and thus the uncertainty in the estimated fractions was lower. Therefore, in these cases we used isotopes instead of EC in the two-component mixing model.

Based on the stated assumptions, the following mass balance equations can be written for periods when only snowmelt and groundwater contributed to streamflow:

$$SF = SM + GW,$$

$$1 = sm + gw,$$

$$\delta_{SF} = sm \cdot \delta_{SM} + gw \cdot \delta_{GW},$$

$$EC_{SF} = sm \cdot EC_{SM} + gw \cdot EC_{GW},$$

where SM, GW and SF denote snowmelt, groundwater and streamflow, respectively; sm and gw indicate the streamflow fraction due to snowmelt and groundwater, respectively; and the notations $\delta$ and EC are used for the isotopic composition and the EC of each component, respectively. Equations (1)–(4) can be solved for the unknown sm as follows:

$$sm(\%) = \frac{\delta_{SF} - \delta_{GW}}{\delta_{SM} - \delta_{GW}} \cdot 100$$

or, using EC,

$$sm(\%) = \frac{EC_{SF} - EC_{GW}}{EC_{SM} - EC_{GW}} \cdot 100.$$  

The gw component can then be calculated by Eq. (2). Analogously, the following mass balance equations can be written for periods when snowmelt, glacier melt and groundwater contributed to streamflow:

$$SF = SM + GM + GW,$$

$$1 = sm + gm + gw,$$

$$\delta_{SF} = sm \cdot \delta_{SM} + gm \cdot \delta_{GM} + gw \cdot \delta_{GW},$$

$$EC_{SF} = sm \cdot EC_{SM} + gm \cdot EC_{GM} + gw \cdot EC_{GW},$$

where in additions to the symbols used in Eqs. (1)–(6), GM denotes glacier melt, and gm indicates the streamflow fraction due to glacier melt. Equations (7)–(10) can be solved for the unknown sm and gm as follows:

$$sm(\%) = \frac{(\delta_{SF} - \delta_{GW}) \cdot (EC_{GM} - EC_{GW}) - (\delta_{SM} - \delta_{GW}) \cdot (EC_{SF} - EC_{GW})}{(\delta_{SM} - \delta_{GW}) \cdot (EC_{GM} - EC_{GW}) - (\delta_{GM} - \delta_{GW}) \cdot (EC_{SM} - EC_{GW})} \cdot 100,$$

$$gm(\%) = \frac{(\delta_{SF} - \delta_{GW}) \cdot (EC_{GM} - EC_{GW}) - (\delta_{SM} - \delta_{GW}) \cdot (EC_{SF} - EC_{GW})}{(\delta_{SM} - \delta_{GW}) \cdot (EC_{GM} - EC_{GW}) - (\delta_{GM} - \delta_{GW}) \cdot (EC_{SM} - EC_{GW})} \cdot 100.$$  

The gw component can be then calculated by Eq. (8).

The uncertainty of the end-member fractions calculated through the two-component mixing model was quantified following the method of Genereux (1998) at the 70 % confidence level. The uncertainty of the end-member fractions calculated through the three-component mixing model was determined by varying the isotopic composition and EC of each end-member by ±1 SD (standard deviation) (Carey and Quinton, 2005; Engel et al., 2016). All mixing models were applied using both $\delta^{2}H$ and $\delta^{18}O$ data; however, results based on $\delta^{18}O$ measurements showed a greater uncertainty than those derived from $\delta^{2}H$ data due to the instrumental performance (Penna et al., 2010). Thus, all results related to isotopes reported in this study are based on $\delta^{2}H$ data.

### 3.4 Scenarios of mixing model application

The spatial and temporal variability of an end-member tracer signal is usually very difficult to characterize at the catchment scale (Hoeg et al., 2000), especially in glacierized catchments (Jeelani et al., 2016), and it can noticeably affect the uncertainty of the results of mixing models. Since field measurements cannot reliably capture such a large spatial and temporal variability, we identified four different scenarios of mixing model application, assuming that they were representative for this variability. The four scenarios differed considering the groundwater end-member based on springs or stream locations during baseflow conditions, and time-invariant or monthly variable isotopic composition and EC
Table 2. Summary of the properties of the end-members used in the four mixing model scenarios for 2013 data.

* For S8 only one sample was collected during baseflow conditions due to the difficult accessibility of the location in fall and winter; therefore, no standard deviation could be computed, and the instrumental precision was used for the computation of the uncertainty of the estimated fractions.

of the snowmelt end-member (Table 2). Particularly, in scenarios A and C, the groundwater end-member was based on the average isotopic composition and EC of samples taken from springs during baseflow conditions in fall of the three study years (springs were not sampled during winter due to limited accessibility of the area), which is consistent with Engel et al. (2016) (Table 3). This assumes a negligible influence of the inter-annual variability of the climatic forcing on the tracer signal of spring water during baseflow. In scenarios B and D, the groundwater end-member was defined as the average of the tracer signal of different stream samples taken during baseflow conditions (late fall and winter of the three study years), at the four Saldur River locations selected in 2013 (Table 3). For the definition of these two groundwater-end-members, we selected the samples taken during baseflow conditions when we assumed that there was no or negligible contribution of snowmelt, glacier melt and rainfall to streamflow. It is important to note that we consider as groundwater components both the spring baseflow and the stream baseflow, because the hydrochemistry of streams during baseflow conditions generally integrates and reflects the hydrochemistry of the (shallow) groundwater at the catchment scale (Sklash, 1990; Klaus and McDonnell, 2013; Fischer et al., 2015).

In scenarios A and B, the tracer signature of the snowmelt end-member was considered time invariant (Maurya et al., 2011) (Table 4). Following Engel et al. (2016), the high-elevation (2800 m a.s.l.) snowmelt isotopic composition was identified through the regression analysis of snowmelt samples collected at different elevations in June 2013, according to Eq. (13) ($R^2 = 0.616$, $n = 7$, $p < 0.05$):

$$\delta^2H(\%o) = -0.0705 \cdot \text{elevation(m a.s.l.)} + 37.261.$$  \hspace{1cm} (13)

EC$_{SM}$ was based on the average EC of all snowmelt samples collected in 2013, without applying any regression-based modification.

In scenarios C and D, the isotopic composition of a high-elevation snowmelt end-member was considered seasonally variable, taking into account that water from the melting snowpack typically undergoes progressive fractionation and isotopic enrichment over the season (Taylor et al., 2001; Lee et al., 2010) (cf. Sect. 4.1). A depletion rate of $-7.0\%o$ in $\delta^2$H
for 100 m of elevation rise was derived from Eq. (13), and
used to estimate the isotopic composition of high-elevation
snowmelt from snowmelt samples collected monthly at dif-
f erent elevations from May to August 2013 (Table 4). Anal-
ogously, the average EC of snowmelt samples taken monthly
was adopted.

In scenarios A and B, Eq. (13) was applied to
snowmelt samples collected at different elevations (lower
than 2800 m a.s.l.) in order to estimate the average isotopic
composition of high-elevation snowmelt, and thus to define a
temporally fixed end-member isotopic composition that was
used in the calculations of streamflow-component fractions
for each sampling date (Table 4, scenarios A and B). In sce-
narios C and D, Eq. (13) was applied to snowmelt samples
collected at different elevations (lower than 2800 m a.s.l.)
and at different times of the melting season in order to es-
timate the seasonally variable isotopic compositions of high-
elevation snowmelt, which were used in the calculations of
streamflow-component fractions for each sampling (Table 4,
scenarios C and D).

For all scenarios, the isotopic signature and EC of the
glacier melt end-member was considered monthly variable
(Table 5 and Sect. 4.1).

4 Results

4.1 Isotopic composition and EC of the different water
sources

Snowmelt sampled from snow patches in summer 2012
and 2013 ranged in δ2H from −106.1 to −139.5 ‰ and
in EC from 3.2 to 77.0 µS cm−1. Glacier melt displayed a
marked enrichment in heavy isotopes over summer, particu-
larly in 2013 (Table 5). The spatial variability in the isotopic
composition of glacier melt was generally small, with spatial
standard deviations ranging between 1.3 and 6.5 ‰. The EC of
glacier melt was very low and little variable in space and in
time (average: 2.1 µS cm−1; standard deviation: 0.7 µS cm−1;
n = 16) for 2012 and 2013 overall, even though a slight pro-
gressive increase in EC was observed in 2013 (Table 5).

The Saldur catchment was characterized by a marked vari-
ability of tracer signature within the same water compart-
ment (i.e. main stream water, tributary water, groundwater)
both in time and in space (Table 6, Figs. 2 and 3). There
was a statistically significant difference in δ2H and EC be-
tween the Saldur River and its sampled tributaries for the en-
tire sampling period (Mann–Whitney test with p < 0.001,
respectively). On average, stream water showed
more isotopically negative and variable values and had lower
EC and higher variability in summer than in fall and winter.
Moreover, the main stream had more depleted isotopic com-
position and lower EC compared to the tributaries (Table 6).

Spring water was the most enriched water source during the
fall but became more depleted compared to stream water dur-
ing the summer when it also showed higher EC. The coeffi-

* Because the isotopic composition of the high-elevation snowmelt end-member was derived by a regression (Eq. 11), the standard deviation was not
computed. Thus, the computation of uncertainty was based on the standard error of the estimate of the regression (6.0 ‰) instead of the standard
deviation of the samples averaged for each month. b Because no snowmelt samples were collected in September and October, the August value was
used also for the two sampling days in September and October. * In May 2013, only one snowmelt sample was collected; therefore, no standard
deviation could be computed, and the instrumental precision was used for the computation of the estimated fractions.

* Summer is considered between mid-June (21) and end of September (23), and fall–winter between end of September and end of March (21).
Overall, the four scenarios provide similar patterns of meltwater dynamics with higher similarities between scenarios A and B, and between scenarios C and D. Indeed, strong correlations exist between the estimates of the same component, with \( R^2 \) for all possible combinations ranging between 0.91 and 0.997 for groundwater, 0.68 and 0.94 for snowmelt, and 0.74 and 0.94 for glacier melt (\( n = 22, \ p < 0.01 \) for all correlations). Despite the general agreement, differences in the estimated streamflow components among the four scenarios do exist. Particularly, scenarios C and D yield higher overall proportions of snowmelt compared to scenarios A and B, and scenarios A and D provide the overall highest and smallest fraction of glacier melt, respectively. Furthermore, scenarios C and D provide larger proportions of snowmelt and smaller proportions of glacier melt in July compared to the two other scenarios (Fig. 5). Overall, the uncertainty associated with the computation of the streamflow fractions is larger for scenarios A and C than for scenarios B and D (compare the length of error bars in Fig. 5).

It is worth mentioning that different proportions of meltwater components at the same stream location could be estimated according to the sampling time of the day. For the melt-induced runoff events sampled at high temporal resolution in 2011, 2012 and 2013 (Engel et al., 2016), the maximum contribution of meltwater to streamflow occurred at the streamflow peak or within an hour after the streamflow peak in 79\% of the observations, whereas the maximum contribution of meltwater was observed within 2 h before the streamflow peak in the remaining 21\% of the cases. Therefore, sampling several hours before or after the streamflow peak can lead to an underestimation of the meltwater fractions in streamflow (Fig. 6). However, the differences in meltwater fractions between samples collected at the streamflow peak and samples collected after the streamflow peak are lower and less variable (shorter error bars) than the ones computed before the streamflow peak (Fig. 6).

4.3 Relation between the two tracers, streamflow and meltwater fractions

The relation between \( \delta^2 \text{H} \) and EC of stream water samples collected at S5-USG and S3-LSG on the same days in 2011, 2012 and 2013, and grouped by month, shows different behaviours according to the sampling period (Fig. 7). Overall, sampling days in May, June and September were characterized by lower mean daily temperatures and stream discharge, much higher EC and more depleted isotopic composition compared to sampling days in July and August (Table 7). The relation between the two tracers is statistically significant in the colder months, whereas it is more scattered and not statistically significant during the warmest months (Fig. 7). The range of \( \delta^2 \text{H} \) values was slightly larger in the mid-summer period compared to May, June and September (16.7 \( \%e \) vs. 15.1 \( \%e \)); on the contrary, the range of EC values was much larger in the spring–late summer period compared to July and August (173.9 \( \mu \text{S cm}^{-1} \) vs. 77.1 \( \mu \text{S cm}^{-1} \)).

Streamflow during the summer-melt runoff events sampled hourly in 2011, 2012 and 2013 at the two monitored cross sections S5-USG and S3-LSG (Engel et al., 2016) is positively correlated with the fraction of meltwater (snowmelt plus glacier melt components) (Fig. 8). Streamflow is presented for comparison purposes both in terms of specific discharge and relative to bankfull discharge, the latter being estimated in the two reaches based on direct observations during high flows. A closer inspection of the figure reveals the occurrence of hysteretic loops between stream-

Figure 3. Spatio-temporal patterns of $\delta^{2}$H (a) and EC (b) for samples taken on the same day at all locations in 2011 and 2012. Location T1 and T3 are excluded because sampled only for 1 year. White cells indicate no available measurements. In 2013, samples were collected only at some locations (Table 1) and therefore, for consistency, 2013 data are not reported here.

Figure 4. Relation between $\delta^{2}$H and EC at all locations in the main stream, the tributaries and the springs in 2011 and 2012. Data refer to samples collected at each location on the same days except for T1 and T3, where samples were taken for 1 year only (cf. Table 1). In 2013, samples were collected only at some locations (Table 1) and therefore, for consistency, 2013 data are not reported here.

flow and meltwater at both locations more evident for events on 12–13 July 2011, 10–11 August 2011 and 21–22 August 2013 at S5-USG, due to their magnitude. Nevertheless, a general positive trend between the two variables is observable, with meltwater fractions increasing when streamflow increased ($R^2 = 0.48$, $n = 130$; $p < 0.01$ at S5-USG; $R^2 = 0.26$, $n = 114$; $p < 0.01$ at S3-LSG). The relation between meltwater fractions (computed as average of the results of the four mixing model scenarios) and streamflow is also plotted for the samples taken monthly in 2013, indicated by the stars in Fig. 8. The samples collected during the 2013 campaigns plot consistently with the samples taken during the melt-induced runoff events at both locations, overall agreeing with the positive trend of the meltwater–streamflow relation (Fig. 8).

5 Discussion

5.1 Controls on the spatio-temporal patterns of the tracer signal

Glacier melt was characterized by similar isotopic composition in 2012 and 2013 and, most of all, by a marked isotopic enrichment and a slight EC increase over the summer season (Table 5). Yde et al. (2016) showed similar trends in the isotopic composition of meltwater draining Mikkivakkat Gletscher, Greenland, for two summers, and Zhou et al. (2014) reported an isotopic enrichment in the firn pack during the early melting season on a glacier in the Tibetan Plateau. However, other studies have reported a strong inter-annual variability in the isotopic signature of glacier melt (Yuanqing et al., 2001) or fairly consistent values over time (Cable et al., 2011; Maurya et al., 2011; Ohlanders et al., 2013; Racoviteanu et al., 2013). In our case, since melting of the surface ice determines no isotopic fractionation (Jouzel and Souchez, 1982), as confirmed by glacier melt samples falling on the local meteorological water line (Penna et al., 2014), the progressive enrichment could be explained by contributions from deeper portions of the glacier surface with increasing ablation over the melting season or sublimation of surface ice (Stichler et al., 2001). More data from this and other glacierized sites should be acquired to better assess this variability that we believe must be taken into account in the application of mixing models for the estimation of glacier melt contribution to streamflow in different seasons.

Figure 5. Fractions of groundwater, snowmelt and glacier melt in streamflow for the six sampling days in 2013 at four cross sections along the Saldur River. Left column panels: the isotopic composition and EC of the snowmelt end-member was considered time invariant, and the groundwater end-member was based on spring data (scenario A, a) or on stream data (scenario B, b). Right column panels: the isotopic composition of the snowmelt end-member was considered monthly variable, and the groundwater end-member was based on spring data (scenario C, c) or on stream data (scenario D, d) during baseflow conditions. The error bars represent the statistical uncertainty for each component.

More negative $\delta^2$H values and lower EC observed in the Saldur River and in its tributaries during the summer than during the winter (Table 6) clearly indicate contributions of meltwater, namely snowmelt, typically isotopically depleted, and glacier melt, typically very diluted in solutes. However, differences exist in the tracer signal among the main stream and the tributaries. The much lower EC of the Saldur River in summer compared to the tributaries (Table 6) suggests important contributions of both snowmelt from high elevations and almost solute-free glacier melt to the main stream, but fewer glacier melt contributions to the tributaries. The larger difference of the coefficients of variation between summer and fall–winter in the Saldur River with respect to the tributaries (Table 6) confirms greater inputs of waters with contrasting isotopic signals (depleted snowmelt and more enriched glacier melt) but relatively similar low EC (Maurya et al., 2011). This observation is corroborated by the larger temporal variability (longer error bars) in the isotopic com-
Figure 6. Average difference between the meltwater fraction in streamflow at the time of streamflow peak and the meltwater fraction at different hours from the time of streamflow peak for the melt-induced runoff events at S5-USG and S3-LSG in 2011–2013. Error bars represent the standard deviation. The vertical line indicates the time of streamflow peak.

Figure 7. Relation between $\delta^{2}H$ and EC of samples collected at S5-USG and S3-LSG on the same days in 2011, 2012 and 2013, grouped by month.
D. Penna et al.: Meltwater dynamics and streamflow response

Figure 8. Relation between specific discharge ($q$) and meltwater fraction (%) in streamflow for the melt-induced runoff events in 2011, 2012 and 2013 sampled at hourly timescale (represented by different coloured symbols), and for the monthly sampling days in 2013 at S5-USG and S3-LSG (represented by stars in cyan). Meltwater fractions for the melt-induced runoff events were taken from Engel et al. (2016), while meltwater fractions for the monthly sampling days in 2013 are given by the average of the four different mixing models scenarios (presented in Fig. 5), and error bars indicate the standard deviation. For the double-peak event on 23–24 August 2012 at S5-USG, where a 9 mm rainstorm superimposed the melt event (cf. Engel et al., 2016), only the melt-induced part of the event was considered. Discharge is reported also as fraction of the bankfull discharge $Q_{bf}$ at the two sections.

because glacier melt had very low EC but was not as isotopically depleted as snowmelt. Having multiple tracers is of certain usefulness when investigating water sources and mixing processes (Barthold et al., 2011), especially in highly heterogeneous environments (Hindshaw et al., 2011), and is essential for the identification of various streamflow components. However, it is important to know the periods when only one tracer could be reliably used, at least for assessing meltwater inputs, especially in glacialized catchments where logistical constraints are always challenging.

The hysteretic behaviour observed between streamflow and meltwater fraction for the melt-induced runoff events (Fig. 8) reflects the hysteresis observed in the relation between streamflow and EC (Engel et al., 2016), suggesting contributions from water sources characterized by different temporal dynamics (Dzikowski and Jobard, 2012). The combination of the highest streamflow and the highest meltwater proportion was obtained at both stream sections in June due to the remarkable contribution of meltwater from the relatively deep snowpack in the upper part of the catchment. It is worth highlighting how the meltwater fraction can frequently represent a substantial (> 50 %) proportion of the bankfull discharge, both during snow and glacier melt flows. This implies that the expected progress of glacier shrinking and future changes in both runoff components will likely have important consequences for the morphological configuration of high-elevation streams like the Saldur River, especially in the wider, braided reaches more responsive to variations in water and sediment fluxes (Wohl, 2010).

5.3 Role of snowmelt and glacier melt on streamflow

The spatial and temporal patterns of meltwater dynamics are consistent with those estimated in other high-elevation catchments worldwide. For instance, the dominant role of snowmelt in late spring–early summer and of glacier melt later in summer was observed across different sites in Asia, North America, South American and Europe (Aizen et al., 1996; Cable et al., 2011; Ohlanders et al., 2013; Blaen et al., 2014, respectively). The decreasing contribution of meltwater from the upper to the lower stream locations from June to October shown almost consistently by all scenarios (Fig. 5) is related to the increasing distance from the glacier and catchment size, and decreasing elevation, in agreement with results from other sites (Cable et al., 2011; Prasch et al., 2013; Racoviteanu et al., 2013; Marshall, 2014). Moreover, lateral contributions from non-glacier-fed tributaries and/or tributaries dominated by groundwater increased the groundwater fraction in streamflow as well and proportionally decreased the meltwater fraction (Marshall, 2014; Fan et al., 2015).

Our estimates of snowmelt contribution to streamflow during the melting season are consistent with those reported in other studies (Carey and Quinton, 2004; Mukhopadhyay and Khan, 2015) and with those found in the same catchment during individual runoff events (Engel et al., 2016). It is more difficult to compare our computed fractions of glacier melt in stream water with estimates in other sites because they can be highly dependent on the yearly climatic variability, on the proportion of glacialized area in the catchment and because they are usually reported at the monthly or yearly scale. However, when considering the total meltwater contribution, the computed fractions for the June–August period...
agree reasonably well with those recently estimated at the seasonal scale in other high-elevation catchments by Pu et al. (2013) (41–62, 12 % of glacialized area), Fan et al. (2015) (26–69 %), Xing et al. (2015) (almost 60 %) and at the annual scale by Jeelani et al. (2016) (52, 3 % of glacialized area), and are even higher than those computed by Mukhopadhyay and Khan (2015) (25–36 %). These observations stress the importance of water resources stored within the cryosphere even in catchments with limited extent of glacialized area, such as the Saldur catchment.

Overall, our tracer-based results on the influence of snowmelt and glacier melt on streamflow agree with glacier mass balance results, which revealed important losses from the glacier surface (−428 mm in snow water equivalent) for the year 2012–2013 (Galos and Kaser, 2013). Particularly, the first strong heat wave serving as melting input was observed in mid-June, when the glacier was still covered by snow and no glacier melt occurred (Galos and Kaser, 2013), in agreement with our estimates of snowmelt contributions (Fig. 5). Glaciological results also showed that most of the glacier mass loss occurred at the end of July to mid-August 2013, but glacier ablation in the lower part of the glacier (below 3000 m a.s.l.) was observed until the beginning of October (Galos and Kaser, 2013), corroborating our tracer-based estimates (Fig. 5).

5.4 Sources of uncertainties in the estimated streamflow components

Various sources of uncertainty affect the estimate of the streamflow components when using mixing models in complex environments such as mountain catchments (Uhlenbrook and Hoeg, 2003; Olanderers et al., 2013). In cases of mixing model applications to separate snowmelt from glacier melt and groundwater, thus not considering rainfall, and in the case of no availability of streamflow measurements (in our case at S8 and S1), uncertainty can be mainly ascribed to the precision of the instrument used for the determination of the tracer signal, and the spatio-temporal patterns of the end-member tracer signature. The instrumental precision can be relatively easily taken into account and quantified by adopting statistically based procedures (e.g. Genereux, 1998). However, the spatio-temporal variation in the hydrochemical signal of the end-members is more challenging to capture and can provide the largest source of uncertainty (Uhlenbrook and Hoeg, 2003; Pu et al., 2013). The isotopic composition and EC of shallow groundwater emerging from springs can be very different within a catchment, especially in cases of heterogeneous geology, as well as the tracer signature of streams at different locations even during baseflow conditions (Jeelani et al., 2010, 2015). Indeed, in our case, the highest uncertainty in the estimated component fractions provided by scenarios A and C can likely be ascribed to the spatial variability of the tracer signature of the sampled springs.

The isotopic composition of snowmelt can mainly change according to (i) macro-topography (e.g. aspect determines different melting rates and so different isotopic compositions); (ii) micro-topography, because small hollows tend to host “older” snow with a more enriched isotopic composition compared to sloping areas; (iii) elevation; and (iv) season, with δ values becoming more negative with increasing elevation and more positive over the melting season (Uhlenbrook and Hoeg, 2003; Holko et al., 2013; Olanderers et al., 2013). EC of snow, and therefore, snowmelt can change as well due, for instance, to the ionic pulse at the beginning of the melting season (Williams and Melack, 1991) and/or reflecting seasonal inputs of impurities from the atmosphere (Li et al., 2006), although this variability is usually much more limited compared to that of the isotopes.

In our case, the instrumental precision of the isotope analyzer and the EC meter is relatively low and was entirely taken into account by the statistical assessment of uncertainty we applied. The spatio-temporal variability of snowmelt was addressed by sampling snowmelt at different elevations, aspects and times of the seasons. Finally, we observed very limited spatial patterns but a marked seasonal change in the tracer signature of glacier melt (Table 5) that was taken into account in the mixing model application (Table 2). Despite these efforts, logistical issues related to the size of the catchment as well as practical and safety issues related to the accessibility of most areas of the catchment, not only in winter, and, not last, economical issues prevent a very detailed characterization and quantification of all sources of uncertainty associated with the estimates of the streamflow components at different times of the year and different stream locations. In addition, an underestimation of meltwater fractions due to sampling time not always corresponding to the streamflow peak should be considered (Fig. 6). Specifically, the samples taken on 19 June at S5-USG and S3-LSG were collected almost 4 h before the streamflow peak. This means that an additional contribution of snowmelt almost up to 20 % could be expected (Fig. 6). As far as we know, these results have not been reported elsewhere and are critical for a proper assessment of the uncertainty in the estimated component fractions. Moreover, these observations suggest that adequate sampling strategies are critical (Uhlenbrook and Hoeg, 2003) and must be considered when planning field campaigns aiming at the quantification of meltwater in glacialized catchments.

5.5 Conceptual model of streamflow components dynamics

The findings from our two previous studies (Penna et al., 2014; Engel et al., 2016) and from the present work allow us to derive a conceptual model of streamflow and tracer response to meltwater dynamics in the Saldur catchment (Fig. 9). To the best of our knowledge, this is the first study to present such a conceptual model of streamflow-component dynamics. Although intuitive, this conceptualization is im-
Figure 9. Conceptual model of the seasonal evolution of streamflow contributions in the Saldur River catchment (closed at LSG). The top subplots in each panel represent the water contributions to streamflow, and the size of the arrows is roughly proportional to the intensity of water fluxes. The bottom subplots show a sketch hydrograph along with EC and isotopic composition of stream water, and the shaded areas indicate time periods corresponding to the top subplots. The winter months, approximately between November and March, when the catchment is in a quiescent state and no significant hydrological dynamics is assumed to occur, are compacted in order to give more space to the other seasons.

Important because it represents a paradigm that, given the characteristics of the study site, can be applied to many other glacierized catchments worldwide.

During late fall, winter and early spring, precipitation mainly falls in form of snow, streamflow reaches its minimum and is predominantly formed by baseflow. EC in stream water is highest and the isotopic composition is relatively enriched, reflecting the groundwater signal. In mid-spring the melting season begins. The snowpack starts to melt at the lower elevations in the catchment and the snow line progressively moves upwards; stream water EC begins to decrease due to the dilution effect and $\delta$ values become more negative, reflecting the first contribution of snowmelt (19–39%). In late spring and early summer the combination of relatively high radiation inputs and still deep snowpack in the middle and upper portion of the catchment provides maximum snowmelt contributions to streamflow (up to $79 \pm 6\%$ in the Saldur River at the highest sampling location) which is
characterized by marked diurnal fluctuations and the highest melt-induced peaks. Groundwater fractions in stream water become proportionally smaller. The glacier surface is still totally snow covered; thus, glacier melt does not appreciably contribute to streamflow. EC is very low due to the strong dilution effect and the isotopic composition is most depleted. In mid-summer the snowpack is present only at the highest elevations and the glacier surface is mostly snow free, so that a combined role of snowmelt and glacier melt occurs. Streamflow is characterized by important diurnal fluctuations, but melt-induced peaks tend to be smaller in absolute values than in early summer associated with snowmelt. Although the snowmelt contribution has decreased, EC in the main stream is still very low due to the input of the extremely low EC of glacier melt. On the contrary, the stream water isotopic composition is less depleted compared to late spring and early summer due to the relatively more enriched signal of glacier melt with respect to snowmelt. In late summer snow disappears from most of the catchment and is only limited to residual patches in sheltered locations. The most important inputs to streamflow are provided by glacier melt that reaches its largest contributions (up to 68–71% in the highest monitored Saldur River location). Diurnal fluctuations are still clearly visible but the decreasing radiation energy combined with lower melting supply limits high flows. EC begins to decrease and the isotopic composition to increase. From late spring to late summer low-intensity rainfall events provide limited contributions to streamflow. However, rainfall events of moderate or relatively high intensity can occur so that rain-induced runoff superimposes the melt-induced runoff and produces the highest observed streamflow peaks. In early fall, meltwater contributions are limited to snowmelt from early snowfalls at high elevations and residual glacier melt and the groundwater proportions become progressively more important. Streamflow decreases significantly and only small diurnal fluctuations are observable during clear days. The two tracers slowly return to their background values.

6 Conclusions and future perspectives

Our tracer-based studies (water isotopes and EC) in the Saldur catchment aimed to investigate the water sources variability and the contribution of snowmelt, glacier melt and groundwater to streamflow in order to contribute to a better comprehension of the hydrology of high-elevation glacierized catchments. We highlighted the highly complex hydrochemical signature of water in the catchment and the main controls on such variability. We applied mixing models to estimate the fractions of meltwater in streamflow over a season, not only at the catchment outlet as usually performed in other studies but also at different locations along the main stream. We found that snowmelt dominated the hydrograph in late spring–early summer, with fractions ranging between 50 ± 5 and 79 ± 6% at different stream locations and according to different model scenarios that took into account the spatial and temporal variability of end-member tracer signature. Glacier melt was a remarkable streamflow component in August, with maximum contributions ranging between 8–15 and 68–71% at different stream locations and according to different scenarios. These estimates underline the key role of snowpack and glaciers on streamflow and stress their strategic importance as water resources.

From a methodological perspective, our results showed that during mixed snowmelt and glacier melt periods, EC and isotopes were not correlated due to the different tracer signature of the two sources of meltwater, whereas they provided a consistent pattern during snowmelt periods only. Such a behaviour, which we found hardly reported elsewhere, should be better assessed over longer time spans and in other sites, but suggests possible simplified monitoring strategies in snow-dominated catchments or during snowmelt periods in glacierized catchments. We identified the main sources of uncertainty in the computed estimates of streamflow components, mainly related to the spatio-temporal variability of the end-member tracer signature, including a clear seasonal enrichment of glacier melt isotopic composition. This is a pattern that must be considered when applying mixing models on a seasonal basis and that we invite to investigate in other glacierized environments. Furthermore, this is the first study, to our knowledge, which quantified the possible underestimation of meltwater fractions in streamflow occurring when stream water is sampled far from the streamflow peak during melt-induced runoff events. Again, this raises awareness about the need for careful planning of tracer-based field campaigns in high-elevation catchments.

We developed a perceptual model of meltwater dynamics and associated streamflow and tracer response in the Saldur catchment that likely applies to many other glacierized catchments worldwide. However, some limitations intrinsic in our approach should be considered. For instance, the reduced number of rain water samples collected at the rainfall-event scale over the 3 years did not allow us to fully assess the seasonal role of precipitation on streamflow in relation to meltwater. Furthermore, the use of EC, which integrates all water solutes in a single measurement, cannot differentiate well some water sources and their relation with the underlying geology. Finally, the monthly sampling resolution at different locations is useful to obtain a general overview and first estimates of the seasonal variability of streamflow components but high-frequency sampling can certainly help to capture finer hydrological dynamics. In this context, the results of the present work can serve as a very useful basis for modelling applications, particularly to constrain the model parametrization and to reduce the simulation uncertainties, and therefore to obtain more reliable predictions of streamflow dynamics and meltwater contributions to streamflow in high-elevation catchments.
7 Data availability

Hydrometeorological data from the Mazia Valley are available from the LTERS Mazia website (http://lter.eurac.edu) upon request through the DEIMS (Drupal Ecological Information System) meta-database (https://data.lter-europe.net/deims/site/LTER_EU_IT_097/). Tracer data used in this study are freely available by contacting the authors.

Acknowledgements. This work was supported by the research projects “Effects of climate change on high-altitude ecosystems: monitoring the Upper Match Valley” (Foundation of the Free University of Bozen-Bolzano), “EMERGE: Retracting glaciers and emerging ecosystems in the southern Alps” (Dr. Erich Ritter und Dr. Herzog-Sellenberg-Stiftung im Stifterverband für die Deutsche Wissenschaft) and partly by the project “HydroAlp”, financed by the Autonomous Province of Bozen-Bolzano. We thank the Dept. of Hydraulic Engineering and Hydrographic Office of the Autonomous Province of Bozen-Bolzano for their technical support, G. Niedrist (EURAC) for maintaining the meteorological stations, Giulia Zuecco (University of Padova, Italy) for the isotopic analyses and Stefan Galos (University of Innsbruck, Austria) for sharing glacier mass balance results. The site Matsch/Mazia belongs to the national and international long-term ecological research networks (LTER-Italy, LTER Europe and ILTER).
