Abstract. While the history of a fluvial hydrosystem can provide essential knowledge on present functioning, historical context remains rarely considered in river restoration. Here we show the relevance of an interdisciplinary study for improving restoration within the framework of a European LIFE+ project on the French side of the Upper Rhine (Rohrschollen Island). Investigating the planimetric evolution combined with historical high-flow data enabled us to reconstruct pre-disturbance hydromorphological functioning and major changes that occurred on the reach. A deposition frequency assessment combining vertical evolution of the Rhine thalweg, chronology of deposits in the floodplain, and a hydrological model revealed that the period of incision in the main channel corresponded to high rates of narrowing and lateral channel filling. Analysis of filling processes using Passega diagrams and IRSL dating highlights that periods of engineering works were closely related to fine sediment deposition, which also presents concomitant heavy metal accumulation. In fact, current fluvial forms, processes and sediment chemistry around Rohrschollen Island directly reflect the disturbances that occurred during past correction works, and up to today. Our results underscore the advantage of combining functional restoration with detailed knowledge of the past trajectory to (i) understand the functioning of the hydrosystem prior to anthropogenic disturbances, (ii) characterize the human-driven morphodynamic adjustments during the last 2 centuries, (iii) characterize physico-chemical sediment properties to trace anthropogenic activities and evaluate the potential impact of the restoration on pollutant remobilization, (iv) deduce the post-restoration evolution tendency and (v) evaluate the efficiency and sustainability of the restoration effects. We anticipate our approach will expand the toolbox of decision-makers and help orientate functional restoration actions in the future.

1 Introduction

During the last 2 centuries, numerous engineering works (e.g. channelization or damming), aimed at flood control, navigation improvement, expansion of agriculture or hydropower production, have altered the functioning of European large rivers (Brookes, 1988; Petts et al., 1989; Kondolf and Larson, 1995), including aquatic and riparian habitats and biodiversity (Bravard et al., 1986; Amoros and Petts, 1993; Dynesius and Nilsson, 1994). In order to balance these impacts by recovering fluvial processes (Knighton, 1984; Bravard et al., 1986; Naiman et al., 1993, 1988; Corenblit et al., 2007; Hering et al., 2015) and ecosystem services (Loomis et al., 2000; Acuña et al., 2013; Large and...
Gilvear, 2015), an increasing number of restoration projects have been carried out over recent decades (Kondolf and Micheli, 1995; Wohl et al., 2005). In Europe, this trend has been supported by the Water Framework Directive (IKSR-CIPR-ICBR, 2005; WFD, 2000). Restoration activities progressively target hydromorphological processes and functioning rather than “static” fluvial forms (Jenkinson et al., 2006; Beechie et al., 2010; Arnaud et al., 2015; Jones and Johnson, 2015). Numerous studies have shown that current river functioning results from complex long-term trajectories driven by natural and anthropogenic factors at different spatio-temporal scales (e.g. Brown, 1997; Bravard and Magny, 2002; Gregory and Benito, 2003; Starkel et al., 2006; Ziliani and Surian, 2012). These trajectories provide a relevant basis to infer future trends and management principles (Bravard, 2003; Sear and Arnell, 2006; Dufour and Piégay, 2009; Fryirs et al., 2012). In order to understand the complete range of functional changes, a comprehensive understanding of human-driven channel adjustments over recent centuries therefore appears crucial in river restoration. Despite significant research efforts over the last 2 decades, integrating pluri-secular temporal trajectories into restoration projects remains an exception (Sear and Arnell, 2006; Fryirs et al., 2012).

In large modified hydrosystems such as the Upper Rhine River, the current lateral extent of the floodplain results from past disturbances that occurred during engineering works (Herget et al., 2005, 2007). Hydromorphological dynamics, chemical pollution and depositional processes were strongly impacted by diking along the main channel and disconnection of lateral channels since the beginning of the 19th century (Tümmers, 1999). Several studies have focused on the storage and remobilization of heavy metals (Schulz-Zunkel and Krueger, 2009; Ciszewski and Gryar, 2016; Falkowska et al., 2016; Grygar and Popelka, 2016) and/or organic pollutants in major floodplains worldwide (Lair et al., 2009; Zimmer et al., 2010; Berger and Schwarzbauer, 2016). Most studies concerned with the Rhine focused on the industrialized Lower Rhine region including the Rhine–Meuse delta (Evers et al., 1988; Middelkoop, 2000; Gocht et al., 2001; de Boer et al., 2010). In comparison, the Upper Rhine region is 2 times less contaminated than the lower parts of the Rhine with respect to total concentrations of both polychlorinated dibenzo(p)dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) in sediments and tracers of industrial activity (Evers et al., 1988). However, contamination histories are still not well known and reference studies considering functioning or disturbance histories are missing.

Studying past functioning and disturbance histories as keys to understanding current forms and processes of floodplains can provide insights into current functioning and hydromorphological sensitivity to changes (Kondolf and Larson, 1995; Mika et al., 2010). Historical hydromorphological adjustments should be evaluated on an accurate spatial scale and at a high temporal resolution to identify past evolutionary processes and causal relationships (Bogen et al., 1992; Horowitz et al., 1999). Interdisciplinary and retrospective studies, however, rarely combine different data sources to obtain a comprehensive view of functional changes (Bravard and Bethemont, 1989; Trimble and Cooke, 1991; Lawler, 1993; Gurnell et al., 2003; James et al., 2009; Rinaldi et al., 2013; Lespez et al., 2015). Furthermore, historical studies rarely consider sediment dating and pollution (Bogen et al., 1992; Garban et al., 1996; Horowitz et al., 1999; Woitke et al., 2003).

Within the framework of a functional geomorphological restoration project on Rohrschollen Island, we embarked on an interdisciplinary and retrospective pluri-secular study to provide a holistic understanding of the functional temporal trajectory of the fluvial hydrosystem, rather than to determine reference states. We hypothesized that long-term temporal trajectories allow us to identify driving factors, amplitude and response time of disturbances, and to provide key information to manage functional restoration actions, notably in terms of potential benefits and limits. This approach has the potential to accompany actions of functional restoration in order to maximize efficiency and sustainability, and infer future evolutionary trends. To test these hypotheses, this study combines horizontal (planimetric) and vertical (thalweg evolution, filling chronology) dynamics to (i) show the functioning of the hydrosystem prior to anthropogenic disturbances, (ii) characterize the human-driven morphodynamic adjustments during the last 2 centuries, including sediment transport and deposition processes as well as geochronology, (iii) assess physio-chemical sediment properties (e.g. heavy metals and organic contaminant concentrations) to trace anthropogenic activities and evaluate the potential impact of the restoration on pollutant remobilization (Middelkoop, 2000; Fedorenkova et al., 2013; IKSR-CIPR-ICBR, 2014), (iv) deduce post-restoration evolutionary trends and (v) propose an operational outlook to improve efficiency and sustainability of the restoration of Rohrschollen Island, and by extension of other river restoration projects (Sear et al., 1994; Grabowski and Gurnell, 2016).

2 Study area

With a total length of 1250 km and a drainage basin of about 185 000 km², the Rhine is the third largest river of Europe. Located between Basel and Bingen (Fig. 1a), the Upper Rhine Graben is 35–50 km wide and 310 km long. Hydrology in the southern part of this sector is characterized by a nivo-glacial regime and a mean discharge of 1059 m³ s⁻¹ (1891–2011; Basel gauging station; Uehlinger et al., 2009). Slope decrease and inherited geomorphological factors explain the longitudinal evolution of the channel pattern from braiding to anastomosing and meandering (Carbiener, 1983; Schmitt et al., 2016; Fig. 1b). Since the middle of the 19th century, three successive engineering works modified drastically the hydrosystem: (i) the correction stabilized the main
channel between two artificial banks and the floodplain between two high-flow dikes, (ii) the regularization consisted in building alternative in-channel groyne fields to improve navigation and (iii) the canalization by-passed the corrected main channel in many areas south of Strasbourg. Nowadays, the river consists of a single channel which is locally by-passed by artificial canalized sections. North of Strasbourg, the canalization concreted the Rhine bed itself.

The artificial Rohrschollen Island is located 8 km southeast of the city of Strasbourg and owes its existence to the construction of a power plant in 1970. Before engineering works, it was a braiding and anastomozing fluvial hydrosystem. The island is enclosed by the Rhine canal to the west and the Old Rhine River to the east, which corresponds to the by-passed corrected Rhine (Fig. 1c). On the southern part, a diversion dam diverts up to 1550 m$^3$ s$^{-1}$ for usage by the power plant. When the discharge is less than 1563 m$^3$ s$^{-1}$, an instream discharge of 13 m$^3$ s$^{-1}$ flows to the Old Rhine. On the northern part of the island, an agricultural dam built in 1984 maintains a constant water level in the Old Rhine at 140 m NN (Normal Null) in order to increase groundwater level for agricultural purposes. When floods exceed 2800 m$^3$ s$^{-1}$ (2-year instantaneous flood), the agricultural dam can be raised for flood retention (IKSR-CIPR-ICBR, 2012), but flooding remains static and only a part of the island is flooded. The island is crossed by an anastomosing channel (Bauerngrundwasser), which is disconnected from the Rhine Canal at its upstream extremity and connects to the Old Rhine further downstream (Fig. 1c, d). Further north an additional minor channel flows towards the Rhine Canal. The water level of the entire length of the Bauerngrundwasser is artificially maintained by the hydraulic backwater of the agricultural dam. Classified as a natural reserve since 1997, the island has recently been restored (European LIFE+ project) in order to recover typical alluvial processes and biodiversity, including dynamic floods, bedload transport, active morphodynamics, and hygrophilous tree species. To attain these objectives, a large floodgate was built in 2013 in the southern part of the island and a new upstream channel of 900 m length was excavated (Fig. 1c, d). The downstream end of this channel is connected to the Bauerngrundwasser channel. Water input from the flood gate ranges from 2 m$^3$ s$^{-1}$ (when $Q_{\text{Rhine}} < 1550$ m$^3$ s$^{-1}$) to 80 m$^3$ s$^{-1}$ (when $Q_{\text{Rhine}} > 1550$ m$^3$ s$^{-1}$). As the bankfull discharge of the new channel is 20 m$^3$ s$^{-1}$, flooding in the island occurs when the discharge exceeds this threshold. A 3-year monitoring
showed that bedload transport and active lateral and vertical morphodynamics occur along the new channel (active bank erosion, formation of bars and logjams, enhancement of pool-riffle sequences, increase in groundwater–surface water exchange; Eschbach et al., 2017, 2018), but not along the Bauerngrundwasser, which is affected by the hydraulic backwater of the agricultural dam (Eschbach et al., 2017, 2018; see also the pictures of Fig. 1). Our study addresses embedded spatial scales: (i) the entire study site, which corresponds to the fluvial hydrosystem area around the natural reserve (about 1–3 km beyond the perimeter of the latter), (ii) Rohrschollen Island, which corresponds to the natural reserve area, (iii) seven transects on the Bauerngrundwasser used to characterize sediment transport and depositional processes, and (iv) two sediment pits excavated near the new and old channels in order to date sediment deposition and assess sediment pollution.

3 Material and methods

In this study, we have adopted an interdisciplinary approach that combines hydrological retrospective modelling with limnometric, topographic (levelling and DEM) and hydrogeologic data as well as data on sediment filling processes, depositional chronology and geochemical characteristics (Fig. 2).

3.1 Planimetric analysis

The historical planimetric analysis covers a period of about 260 years (from 1743 to 2010) and was carried out in ArcMap (ESRI v.10.3) using six historical maps and two sets of aerial photographs. The map from 1828 compiled during the demarcation of the Franco-German border was georeferenced on the IGN BD ortho 2007 base map and used as a base layer for georeferencing of the 1743, 1778, 1838, 1872 and 1926 maps. Aerial photographs were georeferenced using the 2007 orthophotograph as a base layer. Fixed position objects such as churches, road crossings or bank protection structures were used as control points. Between 9 and 12 control points were selected for each historical map, and between 5 and 7 for the aerial photographs. Total root mean square error (RMSE) ranged from 0.94 to 25 m and increased with the distortion and the imprecision of the oldest maps, especially the 1743 and 1778 maps (Fig. 4c). However, the RMSE distortion is satisfactory considering the inherent relative imprecision of these maps and the difficulty in determining anchor points between old maps and 2007 orthophotography. Aerial photographs were selected at low-flow water level to enable comparison between morpho-ecological surfaces and active channel and gravel bar surfaces which are particularly sensitive to discharge variations (Rollet et al., 2014). Morpho-ecological units were then manually digitized at the detailed scale of 1 : 1000 to 1 : 2000 based on eight maps. According to the typology developed by Dufour (2006), 4 classes and 14
subclasses were determined. Surface areas of each class and time slice were calculated to quantify the planimetric evolution. The results of the surface analyses were converted to a percentage ratio to facilitate regional interpretation of the morpho-ecological evolution. Two scales were considered: the study area of Rohrschollen Island with a total surface of 2181 ha and the area of the natural reserve with a total surface area of 314 ha.

### 3.2 Analysis of vertical data

#### 3.2.1 Limnimetric and piezometric analysis

The vertical evolution of the Rhine thalweg was studied based on historical limnimetric data and bibliographic references (Bensing, 1966; Bull, 1885; CECR, 1978). Limnimetric data were compiled for low water discharge (~540 m$^3$/s$^{-1}$) at the Marlen gauging station (Kilometre Point 295; Jeanpierre, 1968; Felkel, 1969). The piezometric analysis was achieved using a German database (LUBW: Landesanstalt für Umwelt, Messungen und Naturschutz Baden-Württemberg) and the French regional groundwater database (APRONA, Association pour la PROtection de la Nappe phréatique de la plaine d’Alsace), by selecting datasets close to the Rohrschollen reach.

#### 3.2.2 Palaeochannel corings

Seven coring transects were distributed along the Bauerngrundwasser to cover the different morphological characteristics of the study area. Six sediment cores per transect were hand-augered on both channel banks to measure the thickness of the post-correction deposits (Fig. 3a). From the 42 cores, a total of 81 sediment samples were taken at different depths of the filling layer. Two additional samples were extracted from the channel bottom at transects two and four with a piston sampler (e.g. Fig. 3a, sample named “C$_{channel}$”).

#### 3.2.3 Pit excavations

In addition to the transect-based prospection, two pits were excavated up to the gravel bottom, on the right bank of the two channels. Locations of the pits were determined by (i) identifying the main filling sectors revealed by old maps and the corings survey, and (ii) the proximity to the potential future erodible banks (concave banks; Fig. 3b). Stratigraphical units (SUs) were defined in the field on the basis of colour and textural differences. Two large topographical cross sections (600 m for pit 1 and 800 m for pit 2) intersecting both pits were extracted from the DEM to interpret the dynamics of fine sediment deposition in relation to the initial elevation.
of each pit, the thickness of the stratigraphical units and the flooding regime (Fig. 3b, c).

3.3 Characteristics of the sediments

3.3.1 Grain-size analysis

Depending on the width and thickness of the filling, 31 samples from three coring transects distributed along the entire length of the Bauerngrundwasser (2, 4 and 5 in Fig. 1) and two samples from the channel bottom (2 and 4 in Fig. 1) were selected for grain-size analysis. In addition, one sample per SU was taken from each excavated pit (Fig. 7). Munsell colour and qualitative SU description were collected in the field. Cumulative grain-size distribution and a sorting index were obtained from measurements with a Beckman Coulter laser diffraction particle size analyser. Then, the soil organic carbon ratio was determined by the loss on ignition method.

3.3.2 Geochemical and organic pollutant analyses

The 10 samples from the two pits (Fig. 7) were air-dried at 20°C and sieved (<2 mm). Dried sediments were pulverized (<63 µm) using an agate disk mill prior to alkaline fusion and total dissolution by acids. Measurement of elemental concentrations was done as described previously (Duplay et al., 2014) by inductively coupled plasma atomic emission spectrometer and mass spectrometer analysis (ICP-AES and ICP-MS) using the geological standards BCR-2 (US Geological Survey, Reston, VA, USA) and SCL-7003 (Analytika, Prague, Czech Republic) for quality control. An enrichment factor (EF) was used to compare changes of Zn, Cr, Ni, Cu, Pb and Cd concentrations in the pit 1 and pit 2 profiles with the reference soil collected in the deepest SU of the considered pit:

\[ EF_{HM} = \frac{HM_{sample}}{HM_{reference}} \cdot \frac{D_{sample}}{D_{reference}}, \]  

where HM and Ti are, respectively, the concentrations of the considered heavy metal and Ti (mg kg\(^{-1}\) d.w.) in the SU sample of the pit and the reference soil. Concentrations of heavy metals were normalized relative to titanium (Ti) as a conservative element to limit EF variations due to local heterogeneities as it displays a low relative standard deviation (<0.03) over both pits (Reimann and de Caritat, 2005).

Based on previous studies dedicated to the contamination of the Rhine sediments (Fedorenkova et al., 2013; van Helvoort et al., 2007), 38 legacy and modern organic pollutants (including 30 pesticides, the hexachlorobenzene and 7 polychlorinated biphenyls) were analysed by liquid chromatography and gas chromatography mass spectrometry (LC-MS and GC-MS) with quantification limits ranging from 0.015 to 0.05 µg g\(^{-1}\) (see Table S1 in the Supplement).

3.3.3 Depositional chronology

Dating of sediments sampled from both pits was carried out using infrared stimulated luminescence (IRSL), as no other alternative approach is achievable in this context (Preusser et al., 2016). The detailed procedures and methodological aspects are discussed in Preusser et al. (2016). In summary, IRSL (stimulated at 50°C) of sand-sized feldspar grains was measured by applying both small-aliquot (ca. 100 grains) and single-grain techniques. When applying the Minimum Age Model (MAM) to single-grain data sets, the estimated ages coincide with the expected age of the sediment. At the same time, MAM ages calculated for the small-aliquot data sets overestimate the known age by up to 200 years (>100%). This is explained by partial resetting of the IRSL signal prior to deposition and masking effects when measuring several grains at the same time. Presented here are the results previously published by Preusser et al. (2016) from pit 1 together with additional samples taken from pit 2 (Table S1). For the new data, we again observed significant older ages when measuring several grains at the same time for most of the samples. Only for sample IDEX2-107 did multiple and single-grain approaches give the same result. However, for this sample overly small grains (100–150 µm) were measured using Risø single-grain discs. This results in accumulation of a few (ca. five) grains being measured at the same time and likely similar averaging effects as observed for larger aliquots. Hence, we consider these ages as maximum estimates.

3.3.4 Flooding frequency assessment

To determine the depositional chronology of the two pits and reconstruct flooding frequency over time, we developed a simple flooding model based on (i) the results of the vertical evolution of the corrected Rhine thalweg close to Rohrschollen Island, (ii) the thickness of fine sediments at both pits, and (iii) IRSL dating. Elevation of the pits at each time slice was determined by the gradual sediment accumulation and the corresponding elevation increase between the two adjacent IRSL dates. Active channel width in the vicinity of the pits was measured from the 1828, 1838, and 1872 maps. Flooding water depth was determined by subtracting the elevation of the pits from the thalweg elevation for each time slice (Fig. 5c). For the three dates corresponding to the 1828, 1838, and 1872 maps, we determined the maximum discharge using the hydrogram (\(Q_{\text{max}}\)) at Basel and the limnimetric data at the Kehl bridge, which is located about 7 km downstream from the study area. We calculated for these dates and the corresponding bankfull discharges.
the sections $S$ (m$^2$), the mean water slopes $I$ (m m$^{-1}$), the hydraulic radius $R_h$ (m), and the roughness $k$ (m$^{1/3}$ s$^{-1}$) close to the pits. This allowed us to estimate flood discharges ($Q_{\text{flooding}}$) for both pits during the entire period from 1828 to 1970 (end of the canalization) using the Manning–Strickler equation (Eq. 2):

$$Q_{\text{flooding}} \text{ pit}_x \text{ at date}_{x_n} = S_{\text{date}_{x_n}} \times I_{\text{date}_{x_n}}^{1/2} \times R_h^{2/3}_{\text{date}_{x_n}} \times k.$$  

Finally, we compared these results with the limnometric variations (historical hydrogram) to determine the frequency and the intensity of historical floods in each pit (Fig. S2 in the Supplement; Fig. 5c).

4 Results and discussion

4.1 Hydromorphological dynamics before the beginning of the correction works (up to ca. 1833)

Analysis of the three earliest historical maps (Fig. 4a, 1743, 1778 and 1828) at the scale of the entire study site documents the natural morphodynamics along the Upper Rhine before the beginning of the correction works. At that time, the Rhine was a wide and braiding channel system (width ranging from 500 to 1500 m) characterized by numerous in-channel gravel bars, which is consistent with the descriptions from Schäfer (1973) and Herget et al. (2005). Multiple anastomozing channels also existed along the floodplain (Carbiner, 1983), at a maximum distance of about 5 km from the thalweg. The braiding and anastomozing index ranged between 7.9 and 5.4 (Fig. 8). The period 1743–1828 is characterized by marked changes and strong channel shifting of about 1 to 2 km. Across the entire study area, gravel bar surface areas increased (+100 ha; +128 %), while vegetated areas changed only slightly (low vegetation: −45 ha; −18.4 %; high vegetation: +124 ha; +11 %; Fig. 4b). In 1828, more than 70 % of the present natural reserve area was occupied by the active channel (running water and gravel bars). The high morphodynamic activity may be caused by the high frequency of flood events (four 10-year floods from 1810 to 1828) characterizing the beginning of the 19th century (Fig. 5c). These dynamics could be an effect of the Little Ice Age (Martin et al., 2015; Schmitt et al., 2016), which may have had a considerable impact on discharge, bedload transport and flood regime intensifying lateral dynamics (Schirmer, 1988; Rumsby and Macklin, 1996). A similar phenomenon has been observed previously, for example, by Bonnefont and Carcaud (1997) on the River Moselle, or by Bravard (2003) for the Rhône Basin. However, this hypothesis has not been validated for the Rhine yet and awaits further testing (Wetter et al., 2011; Schmitt et al., 2016).

At the scale of the natural reserve, the reach was located on the left bank of the Rhine in 1743. It was almost completely occupied by the thalweg from 1778 to 1828 as it shifted towards the western direction. According to the location of pit 1 (Fig. 4a, central bar on the 1828 map) and the depositional history deduced from historical maps, the resetting of the IRSL signal in basal sediments of pit 1 resulted from this major lateral migration (Preusser et al., 2016). In accordance with the IRSL dates, deposition of fine-grained sediments in the lower part of pit 1 took place between 1778 and 1806 (Fig. 5a) after the Rhine thalweg had moved over the area. The maximum age of the investigated sediments in pit 1 is therefore 238–210 years (i.e. 1777–1805; Preusser et al., 2016). The 1828 map in Fig. 4a shows that pit 2 is located in the main channel and accumulation of fine sediments must have commenced after this time. Despite local diking on the floodplain and across some lateral channels as revealed by the planimetric analyses (essentially in 1828), it seems that fluvial morphodynamics and lateral channel shifts before 1828 were not influenced by anthropogenic disturbances.

4.2 Hydromorphological disturbances during the correction works (1833–1876)

4.2.1 Main channel adjustments

The correction works commenced between 1828 and 1838 (around 1833) and induced major changes to the hydro-system (Tulla, 1825; Herget et al., 2005). A detailed map based comparison of the 1828 and 1838 maps shows that the left bank was eroded in the southern part of the study area (maximum of about 50 m) after 1828 and before (possibly during?) the building of the perpendicular in-channel dike (Fig. 4a, 1838). This is in agreement with the current position of the upstream part of the Bauerngrundwasser (Fig. 9, period A). Subsequently, the Rhine thalweg was artificially shifted towards a western direction by the right bank dike, and then to the east by the perpendicular in-channel dike and the high-flow dike. A large flood ($Q \sim 3800$ m$^3$ s$^{-1}$; 10-year floods; Fig. 5c) occurred in 1831, which was thoroughly documented due to the important damages it caused (Champion, 1863). We hypothesize that this event intensified the morphological adjustments during this period. In 10 years (1828–1838) the surface of running water decreased by 20 ha (5 %) in the entire study area, while the surface area of stagnant water increased correspondingly (plus 75 ha equal to 85 %).

From 1840 onwards, the corrected Rhine channel began to incise (1 cm year$^{-1}$ on average; Fig. 5a) in response to channel narrowing (250 m wide), slope increase and bank stabilization (Fig. 4c, 1872). In addition, areas of gravel bars, flowing water and low vegetation surfaces decreased (by 110 ha = 70 %; 194 ha = 50 %; 121 ha = 67 %, respectively), while areas of high vegetation and agricultural surfaces increased (by 218 ha = 18 %; 183 ha = 700 %, respectively; Fig. 4b). This is interpreted as the consequence of sediment deposition in the disconnected parts of the main channel, inducing channel narrowing, and forest and agricultur-
Figure 4. (a) Diachronic evolution of the whole study area. The black boxes are zooms (scale 1 : 2) of the surroundings of the two pits. (b) Surface evolutions of the morpho-ecological units in the natural reserve (1743–2010) and in the whole study area (1743–1949). (c) Number of anchor points used to georeference old maps and aerial photographs (dotted line) and values of RMSEs (continuous line).

4.2.2 Lateral channel adjustments and filling processes

At the scale of the natural reserve, from 1828 to 1838, the braiding and anastomozing index decreased from 5.36 to 2.45, surface areas of running water decreased (by 21 ha = 13 %), and stagnant water and high-vegetation areas increased. In particular, vegetation populated central bars (Fig. 4a). This general trend became even more marked during the 1838–1872 period (Fig. 4b; the braiding and ana-
Figure 5. (a) Vertical evolution of the Rhine thalweg from 1815 to 1960 based on low water levels ($Q \sim 540 \text{ m}^3 \text{s}^{-1}$) recorded at the Marlen gauging station (Bull, 1885; Bensing, 1966; CECR, 1978). Vertical evolution of the pits linked to the age–depth model and number of floods which attained each pit (triangle), (b) location of the two pits and of the ancient gauging station of Marlen, and (c) discharge of the Rhine at the gauging station of Basel. The period 1810–1870 corresponds to maximum instantaneous annual flows. The period 1870–2015 corresponds to the highest mean daily flow (OFEV: Office Fédéral de l’EnVironnement). The dates with arrows correspond to old maps or aerial photographs (see Fig. 4). The red and green lines correspond to the submersion discharges for pits 1 and 2, respectively. (d) Flood return periods at Basel between 1870 and 2015 (m$^3$ s$^{-1}$; adjustment of Pearson III, OFEV).
tomozing index decreased to 1 in 1872), running water and gravel bar areas declined (by 65 ha = 47 % and 45 ha = 71 %, respectively), and high-vegetation and stagnant water areas increased (by 90 ha = 101 % and 19 ha = 166 %, respectively). This supports the idea that the sequential impacts induced by the correction works along the floodplain (i.e. channel narrowing, expansion of vegetation) were especially dynamic in the upstream part of the Bauerngrundwasser.

The channel filling dynamics are detailed in a CM diagram (Fig. 6a), which shows that graded suspension deposition (QR segment) of sandy loam occurred at transect 2. In addition, Fig. 6a shows a general and concomitant decrease in grain size and sediment sorting from the bottom to the surface, which reveals a decline in flood energy likely induced by channel diversion following the correction. Furthermore, residual T2 samples are located on the RS segment (uniform suspension). They correspond to fine sediments (silt) with sorting and depths are not correlated. These have been deposited on the left bank of the Bauerngrundwasser in low-turbulence conditions likely due to site-specific factors such as topography or vegetation, whose general importance has been underlined by Bravard et al. (2014), Toonen et al. (2015) and Riquier et al. (2015). Such kinds of depositional filling processes in newly by-passed channels have also been documented by Passega (1964, 1977) and Bravard and Peiry (1999).

The analysis of the evolution of the middle part of the natural reserve from 1838 to 1872 revealed that a large gravel bar was deposited behind the left dike of the corrected Rhine channel (Fig. 4a). This clearly resulted from an extreme hydrological event which occurred during the Rhine diking and probably corresponds to the 1852 flood (above 300-year flood; Figs. 5c and 9, period B). This flood event, referred to as the “flood of the century” (6.63 m at the Basel gauging station, i.e. 5.78 m higher than the mean low-flow water level), has been documented in detail, especially by Wittmann (1859), Champion (1863), Eisenmenger (1907) and Pardé (1928). After this flood event, embankment of the Rhine continued but local dike apertures remained open in order to feed some old channels and to enhance filling dynamics (Fig. 4a, 1872). In addition, the downstream part of the Bauerngrundwasser (middle part of the natural reserve) presented an important connection to the Rhine, until its probable disconnection in 1876 (Fischbach, 1878; Casper, 1959). This specific hydrological condition impacted the depositional filling processes, as shown by the processes observed at the downstream part of the Bauerngrundwasser which are mainly characterized by graded suspension (Fig. 6a; T4 and T5 transects). Indeed, the CM diagram shows that energy is higher at T5 than at T4, although T4 is located upstream. Furthermore, the complexity is reinforced by the absence of upward fining in grain size at the surface as shown in the upstream part of the Bauerngrundwasser (Fig. 6b). Similar to the T2 samples, the position of the other T4 samples in the CM pattern corresponds to the mean level of turbulence in the uniform suspension (RS seg-
The frequency of flooding (Fig. 5a, c) and mean sedimentation pits in the floodplain (Fig. 3c), which in turn determine the differences (periods and processes) between the two pits are coincides with a clear increase in vegetation areas shown in a grain-size refinement and sorting decrease (Fig. 5a). It end of the depositional filling periods at both pits occurred ages (min: 1828; Fig. 5a), and was relatively regular. The if any deposits of fine sediments existed in 1828, the filling characteristized by low-energy depositional environments in close nel (Fig. 4b, 1828), which became an overbank area char-
acter. Conversely, pit 2 is located on the 1828 main chan-

nel thalweg (as for pit 2 until 1838) or from secondary chan-
mels (Fig. 5a and 7). This may also explain the heterogeneity of these heavy metals upstream from the study site in the 19th ment gradually increased in the Rhine after 1940, followed by a strong reduction of these pollutants due to the Rhine Action Plan since 1970 (Evers et al., 1988; Middlekoop, 2000; Gocht et al., 2001). Similarly, the normalized REE patterns did not show any significant changes with depth in both pits (Fig. S3). Massive use of REE started after 2000 (Klafer et al., 2014), when sedimentation rates were low on Rohrschollen compared to the period during and immediately after the correction works (Fig. 5).

To evaluate the potential metal pollution resulting from anthropogenic activity, the relative enrichment in minor element concentrations in the sediments was evaluated in the pits accounting for the geochemical background. Depth distribution of minor elements in both pits follows a Sr > Ba > Zr > Cr > REE > Zn pattern. Heavy metal concentrations in pit 1 and pit 2 range from 31 to 196 mg kg\(^{-1}\) for Zn, 64 to 91 mg kg\(^{-1}\) for Cr, 10 to 46 mg kg\(^{-1}\) for Cu, 6 to 42 mg kg\(^{-1}\) for Ni, 12 to 35 mg kg\(^{-1}\) for Pb, and 0.23 to 1.24 mg kg\(^{-1}\) for Cd. Cu, Ni, and Cr enrichment factors in pit 1 and pit 2 remained within the natural background (i.e. normalized concentration profiles showed no enrichment in either profile). This suggests low industrial use of these heavy metals upstream from the study site in the 19th century, which is in agreement with previous results (Middlekoop, 2000; Gocht et al., 2001).

In contrast, Zn enrichment factors decrease with depth in pit 2 (from about 4 to 1), which probably reflects anthropogenic inputs of Zn in SUs 4 to 6 (up to 196 mg kg\(^{-1}\) in SU 6). This is in agreement with previous observations (Ciszewski and Gyrar, 2016) insofar as metal pollution is expected to be greater at a shorter distance from the main channel thalweg (as for pit 2 until 1838) or from secondary channels that are hydrologically connected (as for the Bauerngrundwasser after 1838 for pit 2), compared to a site that is further and less frequently flooded (as for pit 1 after 1828). From about 1860 to the early 1930s, heavy metal concentra-

4.2.3 Geochemistry of the sediment filling

Geochemical data combined with geochemical data confirmed changes in the hydro system and sediment deposition dynamics of Rohrschollen from the beginning of the correction works. Quartz (SiO\(_2\)) is the dominant mineral (ranging from 54 to 63 %; Fig. 7) and does not show any particular trend down the profile in pit 1 and pit 2. MnO, TiO\(_2\) and P\(_2\)O\(_5\) are least abundant in both pits. This shows that the patterns of mineral composition are not directly related to grain size and likely reflect a common sediment source to both pits (Gyrar and Popelka, 2016). However, lower ratios of Al / Si, especially in the lower sediment layers of SUs 2 and 3 in both pits 1 and 2, reflect a general low clay content with dominant sandy (pit 1) or silty (pit 2) sediment textures. This suggests relatively weak soil development and chemical weathering. The uppermost sediment layers of pit 1 and pit 2 differed in organic carbon (C) (16.4 and 27.0 g kg\(^{-1}\), respectively), while organic matter content and organic carbon gradually decrease with depth in both pits. This suggests different temporal trajectories of deposition of organic-rich sediments on the two sites, i.e. the gravel bar (pit 1) and the Bauerngrundwasser (pit 2) until 1838.

Regarding pollution histories, polycyclic aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCB), hexa-
chlorocyclohexanes (HCH) and pesticides (Table S1) could not be detected in both pits. This is in agreement with the proposed chronology of pits filling because the first massive use of modern organic pollutants in the whole Rhine catchment gradually increased in the Rhine after 1940, followed by a strong reduction of these pollutants due to the Rhine Action Plan since 1970 (Evers et al., 1988; Middlekoop, 2000; Gocht et al., 2001). Similarly, the normalized REE patterns did not show any significant changes with depth in both pits (Fig. S3). Massive use of REE started after 2000 (Klafer et al., 2014), when sedimentation rates were low on Rohrschollen compared to the period during and immediately after the correction works (Fig. 5).
tions in the Rhine gradually increased in relation to the pro-
gressive industrialization (Middlekoop, 2000). Heavy metal
enrichment, which is particularly marked for Zn, is there-
fore likely caused by changes in both heavy metal pollu-
tion of the Rhine over the past centuries and sedimentation
rates. Although the main depositional filling at pit 2 ended
around 1872, it was still flooded at least four times after this
date (1876, 1881, 1882 and probably 1910), whereas pit 1
was more rarely and intensively flooded (1876 and probably
1881; Fig. 5c). Moreover, flow patterns during flooding from
1872 onwards likely controlled sedimentation rates of heavy
metal-bound to suspended solids. Overall, our results suggest
that Zn may be a proxy of anthropogenic deposition histories
in the Rhine floodplain, as previously shown in large fluvial
systems (Grygar and Popelka, 2016; Lintern et al., 2016).

In addition, water table fluctuation and regular water sat-
uration by flooding may have changed Zn speciation and
mobilization in SUs 1–3 of pit 2, whereas pit 1 remained
non-saturated (Fig. 8). In the period between floods, under
non-saturated conditions and in the presence of oxygen, ox-
idation of metal sulfur, organic carbon and Fe–Mn oxyhy-
droxide in the upper SU may release heavy metals. High
flood frequency possibly increased vertical transport of sus-
pended solids and chemical re-distribution in pit 2, which
smoothed changes in Zn concentrations with depth (Mid-
delkoop, 2000). During flood events, heavy metals can thus
not only move between the SU, but also be partly transported

Figure 7. Stratigraphical log of the two pits including datings, organic contents, and sedimentological and geochemical results.
into the river water in association with suspended solids, by local surface erosion (Tao et al., 2005). This emphasizes that, in a restoration context, Zn may be mobilized and transported into the Rhine by groundwater table elevation (Ciszewski and Gryar, 2016) linked to flooding frequency increase as well as by bank and surface erosion.

4.3 Adjustments since the end of the correction works (after 1876)

Results of the CM pattern (Fig. 6a) show one sample in group 3 and three samples in group 4 that correspond to the left bank of the Bauerngrundwasser (surface layer). This last depositional period is linked to several large floods (1876, 1882; > 300- and 100-year return periods, respectively; Fig. 5c) of high transport energy leading to suspension (Fig. 6a, group 4) and rolling processes (Fig. 6a, group 3-P). The 1876 flood, which was the major hydrological event during this period, fed the Bauerngrundwasser from upstream. The flood induced relative high-flow conditions with increased sediment transport capacities, which caused grain-size decrease along the channel. This process was particularly pronounced in the coarser P sample, which was deposited on the left bank of the channel close to T2 (Fig. 4a, 1926). As identified on the 1926 map, the flood probably opened a dike near the upstream part of the Bauerngrundwasser (Fig. 4a), which increased flow through the channel. During the same period (1872–1926), the last major planimetric and geomorphic changes occurred downstream from the Bauerngrundwasser close to transect 6 (Fischbach, 1878). In this area, the 1876 flood breached the downstream part of the high-flow dike (Fig. 4a, 1872, 1926), and widened and accentuated channel bends (Fig. 9, period C). The present morphology of the Bauerngrundwasser results from this event. After this flood, all dike apertures were closed, thereby re-inforcing the disconnection between the floodplain and the main channel. This situation was exacerbated by the progressive incision of the corrected Rhine channel (Casper, 1959).

Gravel bar surfaces were progressively covered by high vegetation (more than 60% of the natural reserve area in 1926; Fig. 4b).

The regularization works (1930–1936) induced a second phase of incision (Casper, 1959; Marchal and Delmas, 1959), accentuating the gradual conversion of the Bauerngrundwasser into a wetland (+7 ha). At the same time gravel bars appeared on the groyne fields which extended into the corrected Rhine channel (+13 ha between 1926 and 1949; Fig. 4b). In 1970, this Rhine channel was by-passed by the Rhine canal on which a power plant was constructed. A continuous discharge of up to 1550 m$^3$s$^{-1}$ is diverted towards the Rhine canal, altering the hydrology of the Old Rhine River drastically (Fig. 5c, blue hydrogram). Therefore, groundwater level was lowered by about 0.8 m (Fig. 8). In 1984, the construction of the agricultural dam raised and stabilized the water level of the Old Rhine River at 140.00 m NN, and the groundwater level around 139.60–140.00 m NN, while the amplitude of groundwater fluctuation decreased suddenly from 1.5 to 0.4 m (Fig. S3). The entire Bauerngrundwasser was influenced by this backwater effect, which increased the stagnant water surface (+7 ha in 2010; Fig. 4b). To avoid drying of the Bauerngrundwasser during low-flow and drought periods along the Old Rhine River, an input of 1.5 m$^3$s$^{-1}$ from the Rhine canal feeds the channel by a siphon (Fig. 4b, 2010). This explains the specific modern dynamics of sediment suspension at the bottom of the Bauerngrundwasser (group 5; Fig. 6a). Energy decreases along the channel as shown by the differences between T2-Cbs (C = 500; M = 7) and T4-Cbs (C = 100; M = 6). Similar dynamics were also observed by Peiry (1988) and underscores that in-channel deposition and filling was a current process until the start of the restoration.

4.4 Using Rhine long-term trajectory to enhance efficiency and sustainability: learning from the past to infer restoration guidelines

Combining spatial and temporal scales by overlapping multiple data sources in an interdisciplinary approach appears of crucial importance to (i) determine pre-disturbance dynamics of the hydrosystem, (ii) improve the understanding of the history of the hydrosystem in fine spatio-temporal scales (Brierley and Fryirs, 2008; Belletti et al., 2014; Bouleau and Pont, 2014), and (iii) provide key information to manage restoration projects in efficient and sustainable ways. Indeed, these results allow validation of our three working hypotheses.

4.4.1 Long-term temporal trajectories allow us to identify the driving factors, amplitude and response time of disturbances

The pre-disturbance functioning of the Rhine hydrosystem in our study area, as identified by historical map analysis, and sedimentological and geochronological data, was characterized by a high-energy depositional environment with active braiding–anastomozing, lateral channel mobility and important surface areas of gravel bars and pioneer vegetation. In part, this functioning has been targeted by recent restoration efforts. More specifically, the restoration induced, in the new channel, the recovery of bedload transport, lateral and vertical dynamics, as well as groundwater–surface water exchanges. Our results also highlight that the system has been drastically disturbed from the beginning of the correction works. In addition, the flood regime is an additional and crucial driving factor, inducing important and rapid changes in morphodynamics and sediment deposition, especially in low-elevation areas where floods are relatively frequent, long and intense (palaeochannels; e.g. pit 2). The hydrosystem remained morphologically sensitive to floods throughout the duration of the correction works. From the end of the correction, changes were less marked and also related to a decrease...
in flood energy and frequency. The volume of fine sediment deposition is higher in the upstream part of the Bauerngrundwasser, with a maximum thickness of 1.8 m and a volume of about 400 000 m$^3$ (estimated by combining diachronic planimetric analysis with the thickness of the sediment layer close to the Bauerngrundwasser). A volume of about 800 000 m$^3$ of fine sediments with a mean thickness of about 0.4 m was deposited in the entire Rohrschollen Island up to today. This highlights the fact that impacts of correction works and further engineering works are irreversible because the removal of very large amounts of fine sediments seems unthinkable or extremely difficult. Furthermore, the strong hydrological alteration by the canalization works makes the functional alteration of the hydrosystem irreversible as well. In this constrained context, the main challenge of the restoration was to recover processes as dynamic floods (on the whole island) and an active morphodynamic gravel bed channel in a relatively restricted environment (new channel; see also below). On the basis of an environmental monitoring conducted during 3 years after the end of the restoration works, it appears that these restoration objectives are attained (Eschbach et al., 2017, 2018) and that the restoration choices were relevant.

4.4.2 Assessing potential benefits and limits of the restoration

Fine sediments are mainly located along the Bauerngrundwasser and represent a limitation for restoration purposes, because of the risk of their remobilization from both banks and the channel bottom. As shown by Richards and Bacon (1994) and Boulton et al. (1998), fine sediments (e.g. sand) are a limiting factor for many aquatic biological species. This point is important because fine sediments were relatively scarce in the braiding–anastomozing Rhine hydrosystem prior to the initiation of correction works (Ochsenbein, 1966). Furthermore, another risk concerns potential remobilization of pollutants bound to fine sediments. This risk has also been identified and characterized on the Rhône River by Desmet et al. (2012), Provansal et al. (2012) and Bravard and Gaydou (2015). However, backwater effects induced by the agricultural dam control the water level on the Bauerngrundwasser, even during ecological floods (partly), and thus limit bank erosion. Thus, in the specific case of Rohrschollen Island, both risks are drastically lowered by this local hydraulic constraint. This demonstrates once again the relevancy of the principles of Rohrschollen’s restoration.

Conversely, the new channel dug on a large former in-channel gravel bar (Fig. 1d) exposes a thinner layer of fine sediments along its banks, which are mainly composed of coarse sediments (gravels, pebbles) inherited from the pre-correction Rhine. The backwater effect of the agricultural dam does not affect this channel (except the 100 downstream meters; Eschbach et al., 2017). Consequently, the restoration of this channel induces a recovery of bedload dynamics, lateral channel mobility, and morphodynamic and habitat diversification (Eschbach et al., 2018), which notably stimulate key processes such as downwelling/upwelling hydrological exchanges (Eschbach et al., 2017).

4.4.3 Provide key information to manage functional restoration actions in order to maximize efficiency and sustainability, and infer future evolutionary trends

Efficiency and sustainability are key issues in restoration projects (Bouleau and Pont, 2014; Loomis et al., 2000). For management strategies, knowledge of temporal trajectories is relevant for targeting pre-disturbance processes (Cairns, 1991) and performing hydromorphological process-based restorations (Mika et al., 2010; Rinaldi et al., 2015). It also allows us to identify floodplain areas with high hydromorphological functional potentials, i.e. sectors with thin lay-
Concerning the floodplain compartment, the sedimentation rate is relatively low on Rohrschollen Island (about 0.1 cm year$^{-1}$), but it is higher (by about 1 order of magnitude) in areas where flood intensities and frequencies have been less impacted than Rohrschollen Island, along the non-canalized section of the Upper Rhine (Carbiener et al., 1993; Dister et al., 1990; Frings et al., 2014) and in the Rhine delta (Hudson et al., 2008). This floodplain geomorphological evolution reduces flood retention capacities. It probably will require in the future innovative flood management strategies (Hudson et al., 2008) that may notably be based on floodplain artificial excavations of fine sediments (which could be made more difficult if sediments are polluted) and/or natural fine sediment removal by the restoration of active bank erosion in lateral channels. This also should allow recovery of coarse sediments in the floodplains, a texture which is currently lacking. The long-term (> 100 years) sustainability of the hydro-geomorphological management of the Upper Rhine appears as a key question which is becoming more and more important and is made complex by possible fine sediment pollution.

Morphodynamic (and ecological) fluvial functionality requires relatively high, intense and long flood events superimposed on the mean hydrological regime (Bayley, 1991; Dister, 1992; Gurnell et al., 2012). This is the case on Rohrschollen Island, but following the first flooding events after restoration, a further question arises, among others: how to manage such a highly dynamic environment in the medium/long term? For example, it will probably be necessary to balance a relative sediment deficit in the upstream section of the new channel by artificial gravel augmentations, in the next years/decades (Eschbach et al., 2018).

The sustainability of functional restoration efforts and their management remains an open question: on which timescale, for which compartment and over which spatial scales should they be considered? In this context, it appears crucial to continue the post-restoration monitoring over short (3–5 years) and median (> 5–10 years) timescales to evaluate restoration success (Kondolf and Micheli, 1995; Palmer et al., 2005; Jähnig et al., 2011). This opens up avenues for developing integrative methodological approaches to improve pre-restoration knowledge and to implement post-restoration monitoring and modelling, both in the frame of fluvial hydrosystem temporal trajectories.

5 Conclusions

In this study we show the relevance of considering temporal trajectories in process-based river restoration. An interdisciplinary approach deployed at different spatio-temporal scales has been developed by combining planimetric data with sedimentological, chemical and geochronological analysis, as well as a hydrological model. Prior to anthropogenic disturbances, the hydrosystem was mostly characterized by a high-
energy depositional environment of braiding channels with high lateral mobility and important surfaces of gravel bars and pioneer vegetation. Correction works provoked a drastic temporal trajectory change, by intensifying filling of fine and polluted (Zn) sediments in palaeo-channels and decreasing flood frequency, though some intense floods occurred. In contrast, the floodplain recorded lower deposition rates by quasi-unpolluted sediments. More recently, canalization resulted in very low sedimentation rates but strong hydrological and hydrogeological disturbances.

Our results highlight potential risks that restoration projects may face and need to mitigate along large rivers, for example the removal of fine and potentially polluted sediments by reactivating erosion/deposition processes in former channels. On Rohrschollen Island, this risk is reduced by the backwater effect of the agricultural dam which limits lateral erosion in the palaeo-channel. By contrast, floodplain areas outside palaeo-channels show thin layers of fine sediments and appear more relevant to restore dynamic lateral channels. Managers may benefit from excavating new channels in such areas, as has been performed on Rohrschollen Island. They are even encouraged to develop self-erosion of lateral channels by dynamic floods.

Finally, this research underscores the necessity to base functional river restorations on an interdisciplinary knowledge of hydrosystem past trajectories to maximize restoration efficiency and sustainability. On a practical level, we recommend managers conduct such studies in geomorphological restoration projects, even if they are less detailed than our study presented in this article, for example in the case of financial constraints. They should at least be based on (i) planimetric analysis (old maps and photographs), (ii) sedimentological prospection (hand auger) combined with both a lidar DEM analysis and a rapid study of former large floods and (iii) a physico-chemical analysis of sediments, especially these filling palaeo-channels.
